Biographical Sketch

Alfonso Urso received the Laurea degree in electronic engineering (*Summa cum Laude*), and the PhD degree in systems engineering from the University of Palermo, Italy, in 1992 and 1997, respectively. In 1998, he was with the Department of Computer and Control Engineering, University of Palermo, as Research Associate. In 2000, he joined the High Performance Computing and Networking Institute of the Italian National Research Council (ICAR-CNR), where he is currently a Researcher in systems and computer engineering. From 2007 to 2015 he was coordinator of the research group “Intelligent Data Analysis for Bioinformatics” of the Italian National Research Council. Since January 2016 he is Head of the Palermo branch of the High Performance Computing and Networking Institute of the Italian National Research Council (ICAR-CNR). Since 2001 he has been Lecturer at the University of Palermo. His research interests are in the area of machine learning, soft computing and applications to bioinformatics. Dr. Urso is member of the IEEE (Institute of Electrical and Electronic Engineers), and of the Italian Bioinformatics Society (BITS).

Antonino Fiannaca received the Laurea degree in computer science engineering (Summa cum Laude), and the PhD degree in computer science from the University of Palermo, Italy, in 2006 and 2011, respectively. In 2006, he joined the High Performance Computing and Networking Institute of the Italian National Research Council (ICAR-CNR), where he is currently a Researcher. He is part of the Translational Bioinformatics Laboratory at ICAR-CNR. His research interests are in the area of machine learning, neural networks and bioinformatics.

Massimo La Rosa received the Laurea degree in computer science engineering (Summa cum Laude), and the PhD degree in computer science from the University of Palermo, Italy, in 2006 and 2011, respectively. In 2006, he joined the High Performance Computing and Networking Institute of the Italian National Research Council (ICAR-CNR), where he is currently a Researcher. He is part of the Translational Bioinformatics Laboratory at ICAR-CNR. He is member of Bioinformatics Italian Society (BITS) from 2016. His research interests are in the area of machine learning, data mining and bioinformatics.

Valentina Ravi received her Master Degree in Physics, with Biophysical address (Summa cum Laude), at the University of Study of Palermo, Italy. She has held post-graduate internships at the same University, where she collaborated to tutoring, teaching and dissemination activities. She has done a post-Degree training in the area of interest of data mining and support decision systems at ICAR-CNR of the National Research Council, Palermo. Here she is currently involved in research activities in bioinformatics domain, with the focus on the study of data mining techniques.

Riccardo Rizzo is staff researcher at Institute for high performance computing and networking, Italian National Research Council. His research is focused mainly on machine learning methods of sequence analysis, and biomedical data analysis, and on neural networks applications. He was Visiting Professor at the University of Pittsburgh, School of Information Science, in 2001. He participates in the program committee of several international conferences and has served as editor of some Supplements of the BMC Bioinformatics journal. He is author of more than 100 scientific, 33 of them in international journals, such as "IEEE Transactions on Neural Networks", "Neural Computing and Applications", "Neural Processing Letters", "BMC Bioinformatics". He participates in many national research projects and is co-author of one international patent.

Data Mining: Accuracy and Error Measures for Classification and Prediction

Paola Galdi, University of Salerno, Fisciano, Italy

Roberto Tagliaferri, University of Salerno, Salerno, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

The goal of data mining is that of building learning models to automatically extract knowledge from big amounts of complex data. In supervised learning, prior information is used to train a model to learn latent relationships between data objects. Once the model is trained, it is used to perform predictions on previously unseen data.

According to the type of prediction, we can distinguish between classification, where the output is a categorical class label, and regression, where the model learns a continuous function. In the former task, data are divided into groups according to some discriminative features. In the latter, input features are put into a functional relationship with a variable of interest. In both cases, a method is needed to quantify the performance of a model, i.e., to determine how accurate are its predictions.

During the training phase, measuring accuracy plays a relevant role in model selection: parameters are selected in order to maximize prediction accuracy on training samples. At the end of the learning step, accuracy is measured to assess the model predictive ability on new data. Being learning algorithms trained on finite samples, the risk is to overfit training data: the model might memorize the training samples instead of learning a general rule, i.e. the data generating model. For this reason, a high accuracy on unseen data is an index of the model generalization ability.

The remainder of the article is organized as follows: in Sections “Accuracy Measures in Classification” and “Accuracy Measures in Regression” the main accuracy measures used in classification and regression tasks are presented, respectively. Section “Model Selection and Assessment” explores how accuracy measures can be used in combination with validation techniques for model selection and model assessment. Section “Improving Accuracy” introduces bagging and boosting, two techniques for improving the prediction accuracy of classification models.

Accuracy Measures in Classification

The accuracy of a classifier is the probability of correctly predicting the class of an unlabelled instance and it can be estimated in several ways (Baldi *et al.*, 2000). Let us assume for simplicity to have a two-class problem: as an example, consider the case of a diagnostic test to discriminate between subjects affected by a disease (patients) and healthy subjects (controls). Accuracy measures for binary classification can be described in terms of four values:

- TP or true positives, the number of correctly classified patients.
- TN or true negatives, the number of correctly classified controls.
- FP or false positives, the number of controls classified as patients.
- FN or false negatives, the number of patients classified as controls.

The sum of TP, TN, FP and FN equals N , the number of instances to classify. These values can be arranged in a 2×2 matrix called contingency matrix, where we have the actual classes P and C on the rows, and the predicted classes $\tilde{P}$ and $\tilde{C}$ on the columns.

	$\tilde{P}$	$\tilde{C}$
P	TP	FN
C	FP	TN

The classifier sensitivity (also known as recall) is defined as the proportion of true positives on the total number of positive instances:

$$\text{sensitivity} = \frac{\text{TP}}{\text{TP} + \text{FN}} \quad (1)$$

In the above example, it is the number of correctly diagnosed patients on the total number of subjects affected by the disease.

The classifier specificity (also referred to as precision) is defined as the proportion of true positives on the total number of instances identified as positive (in some contexts, the term specificity is used to indicate the sensitivity of the negative class):

$$\text{specificity} = \frac{\text{TP}}{\text{TP} + \text{FP}} \quad (2)$$

In the example, it corresponds to the number of correctly diagnosed patients among all the positive diagnoses.

A low sensitivity corresponds to a high number of false negatives, while a low specificity indicates the presence of many false positives (see Fig. 1 for an example). According to the context, high rates of false negative or false positive predictions might have

Fig. 1 The trade-off between specificity and sensitivity. In the first panel (a) the sensitivity for the red class is highest since all red dots have been assigned to the same class, but the specificity is low since there are many false positives (blue dots in the red class). In the second panel (b) the specificity for the red class is highest since all points assigned to that class are red, but the sensitivity is low for the presence of many false negatives (red dots in the blue class). In the last panel (c) there is a balance between sensitivity and specificity.

different implications: consider failing to diagnose a sick subject (false negative) versus assigning a treatment to a healthy subject (false positive).

The simplest way to estimate accuracy is to compute the percentage of correctly classified patients (positive instances):

$$PA_{pos} = 100 \cdot \frac{TP}{TP + FN} \quad (3)$$

which is complemented by the percentage of correctly classified controls (negative instances):

$$PA_{neg} = 100 \cdot \frac{TN}{TN + FP} \quad (4)$$

To account for all correctly classified instances, accuracy can be computed as:

$$PA = 100 \cdot \frac{TP + TN}{TP + TN + FP + FN} \quad (5)$$

Another option is to average PA_{pos} and PA_{neg} to obtain the average percentage accuracy on both classes.

$$PA_{avg} = \frac{PA_{pos} + PA_{neg}}{2} \quad (6)$$

F-measure (or F-score or F_1 -score) has been introduced to balance between sensitivity and specificity. It is defined as the harmonic mean of the two scores, multiplied by 2 to obtain a score of 1 when both sensitivity and specificity equal 1:

$$F = 2 \cdot \frac{1}{\frac{1}{sensitivity} + \frac{1}{specificity}} = 2 \cdot \frac{specificity \cdot sensitivity}{specificity + sensitivity} \quad (7)$$

Care must be taken when selecting an accuracy measure in presence of unbalanced classes. Following again the above example, consider the case of a dataset where 90% of the subjects are sick subjects and the remaining 10% consists of healthy controls. Taking into account only the percentage of correctly classified instances, a model which assigns every subject to the patients class would attain an accuracy of 90%. In the same case the F-measure would be equal to 0.95, while the average percentage accuracy on both classes PA_{avg} would yield a more informative score of 45%.

When working with more than two classes, say M , the resulting contingency matrix $X = \{x_{ij}\}$ is a $M \times M$ matrix where each entry x_{ij} is the number of instances belonging to class i that have been assigned to class j , for $i, j = 1, \dots, M$. The sensitivity for class i can then be computed as:

$$sensitivity_i = 100 \cdot \frac{x_{ii}}{n_i} \quad (8)$$

where n_i is the number of instances in class i . Similarly, the specificity for class i is:

$$specificity_i = 100 \cdot \frac{x_{ii}}{p_i} \quad (9)$$

where p_i is the total number of instances predicted to be in class i . The percentage of all correct predictions corresponds to:

$$PA = 100 \cdot \frac{\sum_i x_{ii}}{N} \quad (10)$$

Accuracy Measures in Regression

A regression model is accurate if it predicts for a given input pattern its target value with a low error. Given a vector $\hat{y}$ of N predictions and the vector y of N actual observed target values, the most commonly adopted error measure is the mean squared error, computed as:

$$\text{MSE} = \frac{1}{N} \sum_{i=1}^N (\hat{y}_i - y_i)^2 \quad (11)$$

Another variant is the root mean squared error:

$$\text{RMSE} = \sqrt{\text{MSE}} = \sqrt{\frac{1}{N} \sum_{i=1}^N (\hat{y}_i - y_i)^2} \quad (12)$$

Other measures are based on the absolute difference between predicted and actual values, like the mean absolute error:

$$\text{MAE} = \frac{1}{N} \sum_{i=1}^N |\hat{y}_i - y_i| \quad (13)$$

The above measures have the same scale as the input data. A scale-independent alternative is the relative absolute error, computed as:

$$\text{RAE} = \frac{\sum_{i=1}^N |\hat{y}_i - y_i|}{\sum_{i=1}^N |\bar{y} - y_i|} \quad (14)$$

where $\bar{y}$ is the mean of vector y , and therefore the quantity $\sum_{i=1}^N |\bar{y} - y_i|$ acts as a normalizing factor to get a value between 0 and 1. Multiplying this value by 100 yields the percentage absolute error.

The relative squared error is obtained in a similar fashion:

$$\text{RSE} = \frac{\sum_{i=1}^N (\hat{y}_i - y_i)^2}{\sum_{i=1}^N (\bar{y} - y_i)^2} \quad (15)$$

The choice between squared and absolute error depends on several considerations. For example, squared error emphasizes larger differences while absolute error is more robust to outliers causing occasionally large errors. Squared error is sometimes preferred because of its mathematical properties. Contrary to absolute error, it is continuously differentiable, making analytical optimization easier. In addition, when fitting a Gaussian distribution, the maximum likelihood fit is that which minimizes the squared error. On the other hand, absolute error uses the same unit as the data (instead of square units) and might be more straightforward to interpret.

Model Selection and Assessment

The standard approach when evaluating the accuracy of a model is the hold out method. It consists in splitting the available data in two disjoint sets: the training set, which is fed into the learning algorithm, and the test set, used only to evaluate the performance of the model. Commonly, two thirds of the data items are destined to the training and the remainder is reserved for the testing, but other proportions like 70:30, 80:20 and 90:10 are also adopted. There is a trade-off between the training set size and the test set size: using more data for the training allows to build more accurate models, but with fewer instances in the test set the estimate of prediction accuracy will have a greater variance.

When models depend on one or more parameters, a third set of data, the validation set, is required to perform model selection: several models are trained using only data coming from the training set, with different values for each parameter; from the pool of trained models, one winner is selected as that which achieves the best score according to a given accuracy measure on the validation set; finally, the generalization ability of the model is assessed on the test set. Two separated sets of data are necessary for model selection and assessment because using the validation set for the selection of the final model might introduce bias. Therefore, new unseen data are needed to avoid the underestimation of the true error.

Since the choice of the accuracy measure to optimize greatly affects the selection of the best model, then the proper score should be determined taking into account the goal of the analysis. When performing model selection in a binary classification problem, e.g. when selecting the best threshold for a classifier with a continuous output, a reasonable criterion is to find a compromise between the amount of false positives and the amount of false negatives. The receiver operating characteristic (ROC) curve is a graphical representation of the true positive rate (the sensitivity) as a function of the false positive rate (the so called false alarm rate, computed as $\text{FP}/(\text{FP} + \text{TN})$), as shown in Fig. 2. A perfect classifier, with a 100% true positive rate and no false positives would be represented by a (0, 1) coordinate in the ROC space, while chance level corresponds to the diagonal of the plot. Therefore, a good classifier would be represented by a point near the upper left corner of the graph and far from the diagonal. An indicator related to the ROC curve is the area under the curve (AUC), that is equal to 1 for a perfect classifier and to 0.5 for a random guess.

Fig. 2 Receiver Operating Characteristic (ROC) curve.

The main drawback of the hold out method is that it makes an inefficient use of data using only a part of them for the training, thus providing a pessimistic estimate of the model actual accuracy. For this reason, other approaches have been devised to take advantage of all available data, especially in the case of datasets with few samples. Another limitation of the hold out method is that the outcome depends on the specific choice of training and test set. To address this issue, random subsampling can be used to randomly generate multiple training/test splits and the accuracy is computed as the average accuracy across runs. However, if a class happens to be over-represented in the training set, it will be under-represented in the test set, and vice versa, thus affecting the prediction accuracy estimation. Therefore, stratification can be used to preserve the proportion of classes in both training and test set.

Cross-validation is a technique for accuracy estimation where the original dataset is randomly split into k disjoint sets of the same size. The model to be evaluated is trained k times, selecting in rotation $k - 1$ sets for the training and the k -th for the validation. The final accuracy is the overall number of correctly classified instances in each fold divided by N , the total number of instances in the dataset. When $k = N$, the scheme is called leave-one-out, since in each fold the test set is composed by a single object. As for the hold out method, cross-validation can be repeated multiple times using different random splits to obtain a better estimation of prediction accuracy (In a complete cross-validation scheme, all the $\binom{N}{k}$ possible splits are tested, but this is usually prohibitive in terms of computational costs.) and splits can be stratified to preserve class proportions. The advantage of this approach is that it exploits all available data. In particular, the leave-one-out method tests the model on all the possible N splits, and it is suitable in case of few samples, but it is characterized by a high variance. For this reason, small values for k are usually preferred, like in 5- and 10-cross-validation schemes (Kohavi *et al.*, 1995).

Bootstrap (Efron, 1983) is an alternative to cross-validation that relies on random subsampling with replacement (see Fig. 3 for an example). It is based on the assumption that samples are independently and identically distributed and it is especially recommended when the sample size is small. After n extractions, the probability that a given object has not been extracted yet is equal to $(1 - \frac{1}{n})^n \approx e^{-1} \approx 0.368$, therefore the expected number of distinct instances in the sample is $0.632n$. The 0.632 bootstrap estimate of accuracy, introduced in Efron and Tibshirani (1997), is defined as:

$$\text{acc}_{boot} = \frac{1}{b} \sum_{i=1}^b (0.632 \cdot \text{acc}_i + 0.368 \cdot \text{acc}_{train}) \quad (16)$$

where b is the number of generated bootstrap sample, acc_i is the accuracy obtained with a model trained on sample i and tested on the remaining instances, and acc_{train} is the accuracy of the model trained on the full training set.

Once the accuracy of a model has been estimated on a sample with one of the above methods, the amount of uncertainty associated with it can be described by a confidence interval, a range of values that is likely to contain the true value. Confidence intervals are computed for a given a confidence level expressed as a percentage (commonly adopted values are 90%, 95% and 99%), that is interpreted in the following way: if multiple samples are extracted from the same population and a confidence interval with a confidence level of, say, 90%, is computed for each sample, 90% of intervals will contain the true value (Fig. 4). The width of a confidence interval is affected by the size of the sample and its variability, i.e., a small sample characterized by a high variability would yield larger confidence intervals.

In binary classification problems, confidence intervals for the accuracy estimate can be calculated assuming a binomial distribution for the number of correct predictions on the test set; in other words, each prediction is modelled as a Bernoulli variable whose two possible values correspond to correct or incorrect prediction. In general, when a sufficient number of samples is available, approximated confidence intervals can be calculated assuming a Gaussian sampling distribution.

Fig. 3 An example of bootstrap sampling. Since objects are subsampled with replacement, some classes might be over-represented (yellow marbles in bootstrap samples 1 and 2), others might be under-represented (red marbles in bootstrap samples 1 and 2) or even missing (green marbles in bootstrap sample 3).

Fig. 4 Confidence intervals estimated with 90% confidence level: in 3 out of 30 samples from the same population the confidence intervals do not contain the true value for accuracy.

Fig. 5 The bagging approach. Several classifier are trained on bootstrap samples of the training data. Predictions on test data are obtained combining the predictions of the trained classifiers with a majority voting scheme.

Improving Accuracy

Ensemble methods are a class of algorithms that build models by combining predictions of multiple base classifiers. Two prerequisites for the ensemble of classifiers are that they should be diverse, i.e., predict with different accuracies on new data, and accurate, meaning that they should perform better than a random guess (Dietterich, 2000a). There are several approaches to this

Fig. 6 The boosting approach. A classifier is trained on the original data (a). The weights of misclassified instances (dot size in the figure) are increased (b). A new classifier is trained on the new data set and weights are updated accordingly (c).

problem, the most relevant ones being bagging and boosting. The main idea behind these techniques is to generate many perturbed versions of the original training set on which different classifiers are built. Then, the final classification is obtained with a majority voting scheme, where each classifier expresses its vote for class membership of test instances. Both methods have been shown to outperform prediction accuracies of single classifiers (Quinlan *et al.*, 1996).

Bagging (as depicted in Fig. 5) works by creating several training sets by subsampling with replacement the input data, as in bootstrap sampling: the new sets have the same size of the original training set but with some instances missing and some present more than once. The performance of this method depends on how unstable the base models are: if small perturbations of the training set cause a significant variability in the trained classifiers, then bagging can improve the final accuracy (Breiman, 1996). This approach has been successfully applied in the Random Forest model (Breiman, 2001), where the outputs of an ensemble of Decision Tree classifiers are combined in a final solution.

While in bagging each sample is extracted independently and the different classifiers are trained in parallel, boosting follows an iterative scheme, where at each repetition each object is associated with a weight that reflects the performance of the current classifier. Specifically, weights of misclassified instances are increased while weights of correctly classified instances are decreased (see Fig. 6). Then, at the beginning of the next iteration, objects are sampled from the original training set with a probability proportional to their weights (Dietterich, 2000b). The goal is to guide the training of new models towards a solution that correctly predicts the instances that were misclassified in the original training set, thus affecting accuracy. AdaBoost is a prominent example of this class of methods (Freund and Schapire, 1995; Freund *et al.*, 1996).

Data Mining: Clustering

Alessia Amelio and Andrea Tagarelli, University of Calabria, Rende, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

The term “clustering” in its most general meaning refers to the methodology of partitioning elements in groups according to some common characteristics. Cluster analysis was introduced for the first time in anthropology by Driver and Kroeber in 1932 and in psychology by Zubin in 1938 and Robert Tryon in 1939 (Bailey, 1994; Tryon, 1939) with the need of characterizing the typology of different individuals and cultures. Later, it was used by Cattell in 1943 for trait theory classification in personality psychology (Cattell, 1943). However, clustering analysis developed as a major topic in the 1960 and 1970 when the monograph “The Principles and Practice of Numerical Taxonomy” appeared as a clear motivation on researching the clustering techniques (Sokal, 1963). Later, different books were published about the topic, such as “Les bases de la classification automatique” (Lerman, 1970), “Mathematical Taxonomy” (Jardine and Sibson, 1971) and “Cluster analysis for applications” (Anderberg, 1973) which formalized the problem and presented the clustering approaches.

Starting from 1960, clustering has been used in different disciplines, including biology, psychology, anthropology, political science, sociology and social sciences, geography, economics and literature. In biology, clustering has been applied for counting dust particles and bacteria. In geography, it has been employed for solving problems of land allocation in urban planning. In political science, clustering has been used for supporting tasks of political campaigning (Krippendorff, 1980).

Nowdays, clustering has become a valid instrument for solving complex problems of computer science and statistics. In particular, it is very used in data mining and effective for discovering patterns of specific interest from data in order to support the process of knowledge discovery. Generally, in order to optimize the clustering solution, data are pre-processed before applying a clustering approach. The specific type of pre-processing task mainly depends on the used clustering approach. Pre-processing tasks may include: (i) removal of noise or outliers from data, which is essential when the clustering approach is sensitive to noise or outliers, (ii) data normalization, which is important for distance-based clustering, and (iii) data reduction (sampling or attributes reduction), which can be useful when the clustering approach is computationally expensive. Normalization consists of scaling the data to fall within a given range. Data reduction can remove irrelevant attributes by attribute selection or principal component analysis which finds a lower dimensional space representing the data, or remove instances of data by using a sampling method.

In this article, we present the main concepts underlying the clustering methodology. We start by providing a background of the clustering problem, together with the key elements which are essential for its resolution. Among the others, we present some meaningful distance and similarity measures commonly adopted in the literature for clustering. Then, we provide a full categorization of the main clustering approaches, by describing some relevant and well-known algorithms for each category. It includes the description of clustering methods specifically designed for non-conventional data, such as the images and XML data. A section is also dedicated to the application of traditional clustering methods to data of different domains. Finally, different approaches for the evaluation of a clustering solution are presented and discussed.

The article is organized as follows. Section Background provides a background of the clustering problem. Section Methodologies focuses on the clustering methodologies and algorithms. Section Applications of Data Clustering presents different examples of application of the traditional clustering methods to data in different domains. Section Analysis and Assessment describes some relevant criteria for evaluation and assessment of a clustering solution. Finally, Section Closing Remarks draws conclusions about the presented topic.

Background

Clustering belongs to the category of unsupervised learning, whose aim is partitioning unlabeled data into clusters. The data belonging to the same cluster will be “close” to each other, and “far” from the data belonging to different clusters (Rokach and Maimon, 2005). Various proximity criteria can be used for evaluating how “close” the data are. Basically, the choice of a suitable proximity measure mainly depends on the data typology and on the descriptors which are used for representing the data.

Formally, given a collection of data points $\mathcal{X}$, the clustering consists of partitioning them into K disjoint groups $c_1, c_2, \dots, c_K$ such that the union of these groups provides the original collection of data points $\mathcal{X}$, and their intersection is empty:

- $\mathcal{X} = \bigcup_{i=1}^K c_i$,
- $\forall i \neq j, c_i \cap c_j = \emptyset$.

Fig. 1 shows an example of clustering 39 data points into 4 clusters.

In order to cluster a collection of data points, three elements are of prior importance (Ullman *et al.*, n.d.):

1. The proximity measure (similarity, dissimilarity or distance measure),
2. The function for evaluating the quality of the clustering, and
3. The algorithm for clustering computation.

Fig. 1 A sample of clustering 39 data points into 4 clusters. Clusters are delimited by a dashed line and reported in the legend on the right.

In particular, given two data points x_i and x_j , a similarity measure is a proximity measure achieving large values when x_i and x_j are similar. On the contrary, a dissimilarity measure (or a distance measure) is a proximity measure which obtains small values when x_i and x_j are similar (Ullman *et al.*, n.d.). The function for evaluating the quality of the clustering should discriminate between a “good” and a “bad” clustering. Finally, the algorithms which are used for computing the clustering are based on the optimization of the evaluation function.

Different similarity, dissimilarity and distance measures have been introduced in the literature as proximity measures for the clustering problem. In particular, they can be classified as (Ullman *et al.*, n.d.):

- Euclidean, and
- Non-Euclidean.

The Euclidean measures are based on the concept of Euclidean space, which is characterized by a given number of dimensions and “dense” points. The average of two or more points can be evaluated in the Euclidean space and a proximity measure can be computed according to the location of the points in the space. Three Euclidean measures which have been used for clustering in multiple domains are (Ullman *et al.*, n.d.):

- The Euclidean distance,
- The Manhattan distance, and
- The Minkowski distance.

Let $x_i = \{x_i^1, x_i^2, \dots, x_i^n\}$ and $x_j = \{x_j^1, x_j^2, \dots, x_j^n\}$ be two n -dimensional data points. The Euclidean distance between x_i and x_j is defined as follows:

$$d(x_i, x_j) = \sqrt{\sum_{k=1}^n (x_i^k - x_j^k)^2} \quad (1)$$

An interesting property of the Euclidean distance is that it is invariant to translation. In particular, let $a = \{a^1, a^2, \dots, a^n\}$ be a translation vector. It is observed that the distance in the translated space is equal to the distance computed in the original space:

$$\sqrt{\sum_{k=1}^n ((x_i^k - a^k) - (x_j^k - a^k))^2} = \sqrt{\sum_{k=1}^n (x_i^k - a^k - x_j^k + a^k)^2} \quad (2)$$

The Manhattan (or city block) distance can be considered as an approximate and less expensive version of the Euclidean distance. Given the two n -dimensional data points x_i and x_j , it is defined as follows:

$$d(x_i, x_j) = \sum_{k=1}^n |x_i^k - x_j^k| \quad (3)$$

The generalization of the Euclidean and Manhattan distances is the Minkowski distance, which is defined as:

$$d(x_i, x_j) = \left[\sum_{k=1}^n (x_i^k - x_j^k)^p \right]^{\frac{1}{p}} \quad (4)$$

where p is a positive integer.

Table 1 Overview of some proximity measures adopted in the clustering context

Name	Type	Measure
Euclidean distance	Euclidean	$\sqrt{\sum_{k=1}^n (x_i^k - x_j^k)^2}$
Manhattan distance	Euclidean	$\sum_{k=1}^n x_i^k - x_j^k $
Minkowski distance	Euclidean	$[\sum_{k=1}^n (x_i^k - x_j^k)^p]^{\frac{1}{p}}$
Jaccard distance	Non-Euclidean	$1 - \frac{ x \cap y }{ x \cup y }$
Cosine similarity	Non-Euclidean	$\arccos \frac{x \cdot y}{ x y }$
Edit distance	Non-Euclidean	$ x + y - 2 LCS(x, y) $

The Non-Euclidean measures take into account some specific properties of the data points, which do not include the location of the points in the space. Three Non-Euclidean measures which are well-known in different clustering contexts are (Ullman, n.d.):

- The Jaccard distance,
- The Cosine distance, and
- The Edit distance.

Let x and y be two data points with n elements. The Jaccard distance is defined as follows:

$$d(x, y) = 1 - \frac{|x \cap y|}{|x \cup y|} \quad (5)$$

where $|x \cap y|$ is the size of the intersection and $|x \cup y|$ is the size of the union between the elements in x and the elements in y .

If x and y are considered as two vectors positioned from the origin until their location, the cosine distance is the angle between the two vectors, which is the arccosine of their normalized dot product:

$$d(x, y) = \theta = \arccos \frac{x \cdot y}{|x||y|} \quad (6)$$

Finally, the Edit distance is usually applied when x and y are strings and their elements are the characters composing the strings. It is defined as the number of inserts and deletes which are needed to turn one string into the other one:

$$d(x, y) = |x| + |y| - 2|LCS(x, y)| \quad (7)$$

where $|x|$ and $|y|$ are respectively the size of x and y , and $LCS(x, y)$ is the longest common subsequence of x and y . Table 1 shows an overview of all aforementioned proximity measures.

The evaluation of the clustering quality is generally a hard problem, which includes the two aspects of: (i) cluster compactness, and (ii) cluster isolation (Ullman et al., n.d.). The cluster compactness evaluates the nearness of the data points in a given cluster to its cluster centroid. In the Euclidean space, it is usually computed as the Sum-of-Squared-Error (SSE) measure. In particular, let $c_i = \{x_1, x_2, \dots, x_d\}$ be a cluster of d data points. The SSE computed on c_i is defined as follows:

$$SSE = \sum_{h=1}^d \sum_{k=1}^n (x_h^k - m_i^k)^2 \quad (8)$$

where m_i is the centroid of cluster c_i and m_i^k is the k -th element of the centroid m_i .

The cluster isolation evaluates how far two cluster centroids are in the clustering. In a “good” clustering, the different cluster centroids should be sufficiently distant to each other.

Another important aspect is the number K of clusters in which the data points should be partitioned. Usually, two common strategies can be followed: (i) the number K of clusters is an input parameter of the clustering and it is prior fixed, or (ii) the number K of clusters is dynamically obtained by detecting the best clustering according to the quality evaluation function (Ullman et al., n.d.).

In the next section, we focus on the methods which are currently adopted in the literature for clustering and their applications. Accordingly, we will describe the algorithms which are employed for finding the best clustering and the functions they use for evaluating the clustering quality.

Methodologies

The clustering methods can be partitioned in two broad categories (Xu and Tian, 2015; Ullman et al., n.d.):

- Partitional, and
- Hierarchical.

Fig. 2 Overview of the clustering categorization.

The partitional methods include: (i) centroid-based, (ii) model-based, (iii) graph-theoretic, and (iv) spectral approaches. The Hierarchical methods include: (i) divisive, and (ii) agglomerative approaches. Apart from these two categories, we find the density-based clustering methods and the methods for clustering non-conventional data. **Fig. 2** shows an overview of the presented clustering categories.

Partitional Methods

In the partitional methods, the number K of clusters is usually an input parameter. These methods are based on the relocation of the data points which are moved from one cluster to another one, starting from an initial cluster configuration. Because the global optimality cannot be achieved since it would require an exhaustive enumeration of all possible partitions, these methods use greedy heuristics based on iterative optimization (Rokach and Maimon, 2005). Next, we describe some relevant partitional methods and refer to Celebi (2014) for further details.

Centroid-based approaches

The centroid-based approaches are partitional methods characterized by the concept of cluster centroid, which is the central point (e.g. the mean, the median, etc.) computed for the clusters. Initially, the cluster centroids can be randomly selected. Then, an iterative refinement phase changes the centroids' position and the assignment of the data points to the centroids, until a termination condition is satisfied (Xu and Tian, 2015). Two methods belonging to this category are K-Means and K-Medoid.

K-Means. The K-Means algorithm partitions the data points into K non-uniform clusters, where K is an input parameter (MacQueen, 1967). The first step of the algorithm consists of selecting K initial centroids, one for each cluster. It is a critical choice which may influence the final clustering result. In the second step, each data point is assigned to the nearest centroid in terms of the Euclidean distance function. After that, K new centroids are computed as the mean of the data points for each cluster. The second and third steps are iterated until the centroids modify their location. The K-Means finds the K centroids which minimize the following objective function:

$$J = \sum_{j=1}^K \sum_{i=1}^{n_j} \|x_i^{(j)} - m_j\|^2 \quad (9)$$

where n_j is the size of cluster c_j , $x_i^{(j)}$ is the data point x_i belonging to cluster c_j , m_j is the centroid of cluster c_j , and $\|\cdot\|^2$ is the squared Euclidean distance. The time required by the algorithm is $O(I \times K \times M \times n)$, where I is the number of iterations, K is the number of clusters, M is the total number of data points, and n is the dimension of each data point. Because I is usually small and $K \ll M$, the algorithm is linear in the number M of data points (Tan et al., 2005). However, because it computes the mean value, it is particularly sensitive to the outlier data.

K-Medoid. The K-Medoid algorithm is a more robust version of the K-Means to noise and outliers (Kaufman and Rousseeuw, 1987). Instead of using the mean points as centroids, the algorithm selects the centroids among the data points, which are called medoids. The number K of clusters is the input of the algorithm. The first step randomly chooses K data points as the initial medoids. After that, each data point is assigned to the nearest or most similar medoid. The third step randomly selects a data point o to become the new medoid. Then, the total cost S of exchanging o with its old medoid is computed. If S is negative, then the old medoid is exchanged with o . Steps from 2 to 5 are iterated until the medoids change their location. The total cost S is computed as

the difference between the value of the cost function after and before the exchange of o with the medoid. In particular, the cost function J is defined as follows:

$$J = \sum_{j=1}^K \sum_{i=1}^{n_j} |x_i^{(j)} - \bar{m}_j| \quad (10)$$

where n_j is the size of cluster c_j , $x_i^{(j)}$ is the data point x_i belonging to cluster c_j , and $\bar{m}_j$ is the medoid of cluster c_j . Because the mean computation is not required, the algorithm can be used for clustering data points in Non-Euclidean spaces, too. One iteration of the algorithm takes $O(K \times (M - K)^2)$, which may be expensive for large K and M values.

Model-based approaches

The model-based approaches are partitional methods which associate a model with each cluster. The best fit of that model with the data points corresponds to the output of the procedure. These approaches can be partitioned in two sub-categories: (i) statistical learning, and (ii) neural network learning. A typical algorithm of statistical learning is Gaussian Mixture Model (GMM). A typical algorithm of neural network learning is Self-Organizing-Map (SOM) (Xu and Tian, 2015).

GMM. Let $\mathcal{X} = \{x_1, \dots, x_M\}$ be a set of M data points generated by an unknown probability distribution. The number K of clusters is an input parameter. The aim of this algorithm is to estimate the set of parameters θ of the GMM model which best fits the data points (Allili, n.d.). It is accomplished by maximizing the likelihood $p(\mathcal{X} | \theta)$ of the data points given the parameters θ of the model. Accordingly, the problem is defined as follows:

$$\theta^* = \arg \max_{\theta} p(\mathcal{X} | \theta) = \arg \max_{\theta} \prod_{i=1}^M p(x_i | \theta) \quad (11)$$

In order to maximize the likelihood, the Expectation-Maximization (EM) procedure is used. It is based on a hidden variable, which is added to simplify the maximization of the likelihood. The algorithm is composed of a step of expectation, where the distribution of the hidden variable given the data points and the value of the parameters are estimated. It is followed by a step of maximization, where the hidden variable is used for modifying the parameters in order to maximize the likelihood of the data points and of the hidden variable. The GMM algorithm takes $O(M^2 \times K \times I)$, where I is the number of iterations of the algorithm (Xu and Tian, 2015).

SOM. The Kohonen's SOM algorithm computes the output clusters after a learning phase which models an artificial neural network to follow the "shape" of the training data (Kohonen, 1982). The network is characterized by a set of n input neurons, corresponding to the dimension of the input data point, and by a set of K output neurons, which may correspond to the number of clusters. An output neuron j is associated with a n -dimensional vector of weights $w_j = [w_{j1}, \dots, w_{jn}]$, which is called prototype vector. The training of the network starts at the first epoch by initializing all the weights to small random values. Then, a data point x is randomly selected from the training data and given as input to the network. Hence, the output neuron with the nearest prototype vector from x in terms of Euclidean distance, called Best-Matching Unit (BMU) is selected. After that, all the prototype vectors in the neighborhood of BMU are updated by using the following rule:

$$w_j(t+1) = w_j(t) + \eta(t)(x - w_j(t)) \quad (12)$$

where η is the learning rate which monotonically decreases over time. The procedure is iterated by increasing the epoch number, until the computational bounds do not exceed. A new input data point belongs to that cluster which is associated with its BMU. The temporal cost of the SOM algorithm is $O(S^2)$, where S is the number of the map units.

Graph-theoretic approaches

The graph-theoretic approaches compute a partition-based clustering on a graph, where the nodes are the data points and the edges are the relationships among the data points. Weights can be associated with the nodes and/or the links of the graph, representing the similarity between nodes. Two algorithms belonging to this category are CLICK (Cluster Identification by Connectivity Kernels) and MST-based (Minimum Spanning Tree-based) clustering (Xu and Tian, 2015).

CLICK. The CLICK algorithm is characterized by two main steps (Sharan and Shamir, 2000). In the first one, the algorithm recursively splits the nodes of the graph in connected components according to a minimum weight cut criterion. In particular, if the connected component satisfies a given criterion, then it is considered as a kernel and returned. Otherwise, it is split in two parts based on the minimum weight cut criterion. Also, if the connected component is a singleton node, then it is separately managed. In the second step, an adoption procedure is performed, which iteratively finds the most similar pair of singleton and kernel and assigns the singleton to that kernel if their similarity overcomes a predefined threshold. After that, a merging procedure is applied, which iteratively merges pairs of clusters whose similarity is the highest and overcomes a predefined threshold. At the end, the adoption procedure is repeated on the new set of clusters for generating the final clusters. The temporal cost of the algorithm is $O(K \times f(M, E))$, where M is the number of nodes, E is the number of edges, K is the number of clusters, and $f(M, E)$ is the cost of computing a minimum weight cut (Xu and Tian, 2015).

MST-based clustering. A MST-based clustering algorithm generates a Minimum Spanning Tree (MST) from the graph in order to obtain the clusters (Jain and Dubes, 1988). The first step of the algorithm consists of building the MST from the graph of the data points. After that, the inconsistent edges are identified in the MST. Finally, the inconsistent edges are eliminated from the MST in order to keep the connected components representing the clusters. If the procedure is recursively applied on each

obtained cluster, other sub-clusters can be generated. An inconsistent edge can be found by considering if its weight is larger than the average weight of its neighbor edges, the number of standard deviations, or the ratio between its weight and the average weight of its neighbor edges. If the inconsistency factor of the edge is two, then the edge can be eliminated, because it usually connects two clusters. The algorithm takes $O(E \times \log M)$, which is basically the temporal cost of the Kruskal's algorithm for generating the MST (Xu and Tian, 2015).

Spectral approaches

Spectral clustering approaches are partitional methods which are based on the construction of a similarity graph, where the nodes are the data points, and the weighted edges represent the similarity between the nodes. Then, the graph is partitioned such that the total edge weight is as high as possible in each group and as low as possible between the groups. A typical algorithm belonging to this category is NJW (Ng, Jordan and Weiss) (Xu and Tian, 2015).

NJW. The NJW algorithm constructs the matrix $L = D^{-1/2} W D^{-1/2}$, where W is the similarity matrix corresponding to the graph adjacency matrix, and D is a diagonal matrix summing the weights for each node, $D(i) = \sum_j w(i, j)$. Then, the k largest eigenvectors $e_1, e_2, \dots, e_k$ of L are computed and set as the columns of a matrix $X = [e_1 e_2 \dots e_k] \in \mathbb{R}^{M \times k}$, where M is the number of the data points. After normalizing the rows of X to have unit length, the M rows are clustered by using the K-Means algorithm. Finally, each data point is assigned to that cluster which the corresponding X 's row was assigned to Ng et al. (2001). The algorithm can be quite demanding because of the high cost of an eigenvector method (Xu and Tian, 2015).

Hierarchical Methods

The hierarchical methods build a tree, which is called dendrogram, representing the relationships among the data. Then, they use the dendrogram in order to cluster the data. Hierarchical methods are based on two strategies: (i) agglomerative, and (ii) divisive (Tan et al., 2005). Ref. Murtagh and Contreras (2012) presents an overview of the main hierarchical clustering methods.

Agglomerative approaches

An agglomerative approach (or bottom up) starts by creating one cluster for each data point. Then, pairs of clusters are merged at each step, until all data points are grouped into a single cluster. It generates a hierarchy of clusters represented by a dendrogram from which the final clustering is obtained by cutting the dendrogram to a specific level. The merging procedure is performed between the two nearest clusters according to a linkage method. The three most common linkage methods are: (i) single linkage, (ii) complete linkage, and (iii) average linkage. In the single linkage, the distance between two clusters is equivalent to the distance between their two closest data points, one for each cluster. In the complete linkage, the distance between the two farthest data points, one for each cluster, is considered as the distance between the two clusters. Finally, in the average linkage, the distance between two clusters is the average distance of all pairs of data points in the two clusters (Tan et al., 2005). The temporal cost of this approach is $O(M^2 \times \log M)$, where M is the number of the data points (Tan et al., 2005).

Divisive approaches

A divisive approach (or top-down) starts by condensing all the data point into a single cluster. Then, at each step, the clusters are progressively divided in two new clusters, chosen to maximize the inter-cluster distance. The procedure is iterated until each data point becomes a single cluster. The inter-cluster distance can be computed by using similar linkage methods as in the agglomerative clustering: (i) single linkage, (ii) complete linkage, and (iii) average linkage (Forsyth, n.d.). The divisive approach takes at least $O(M^2)$, where M is the number of the data points.

Density-Based Methods

The density-based methods identify the clusters as regions of high-density, which are separated by regions of low-density. Consequently, the number of clusters does not need to be prior fixed. A well-known algorithm belonging to this category is the DBSCAN (Density-based Spatial Clustering of Applications with Noise) (Tan et al., 2005). A survey describing other density-based methods can be found in Loh and Park (2014).

DBSCAN. The DBSCAN algorithm uses a center-based approach for defining the density. In this approach, the density of a given data point is computed as the number of data points within a radius Eps of that point, which includes the point itself. The size Eps of the radius is an input parameter of the algorithm. According to this approach, a data point can be categorized as follows: (i) a core point, inside a dense region, (ii) a border point, on the edge of a dense region, (iii) a noise or background point, inside a region of low-density. The algorithm starts by categorizing all data points as core, border, or noise. All noise data points are discarded. Then, any two core data points which are within an Eps radius to each other are grouped into the same cluster. At the end of this procedure, all core points are separated in different clusters. Finally, each border data point is assigned to its nearest cluster. The algorithm takes $O(M^2)$ in the worst case, where M is the number of the data points (Tan et al., 2005).

Clustering Methods for Non-Conventional Data

In the last years, different methods have been specifically introduced for clustering non-conventional data, whose representation can be unstructured, such as the images, or semi-structured, such as the XML documents.

Image data clustering. Image data are usually represented by matrices of pixels, where each pixel can be characterized by brightness, color, texture, and shape information. According to this representation, different algorithms have been specifically proposed for clustering in this domain. They can solve the image segmentation problem or the image clustering problem. The first problem has the aim of partitioning the image pixels into uniform regions characterizing the objects of the image. The second problem has the aim of categorizing an image database according to the image properties (color, texture, etc.). In this context, Ref. [Shi and Malik \(2000\)](#) has introduced the SM (Shi and Malik) algorithm, which is a spectral approach for solving the image segmentation problem. It builds a similarity graph which is represented by its weighted adjacency matrix W . Each node is a pixel and edges link spatially close pixels. The algorithm runs by solving the system $(D - W)x = \lambda Dx$ for the eigenvectors with the smallest eigenvalues, where D is a diagonal matrix summing the weights for each node, $D(i) = \sum_j w(i, j)$. The eigenvector with the second smallest eigenvalue is used for finding a splitting point of the graph in two parts such that the normalized cut is minimized. Finally, the algorithm is recursively run on each part until the normalized cut exceeds a given threshold. It determines a division of the pixels into image regions. GeNCut (Genetic Normalized Cut) is a genetic graph-based clustering algorithm extending the SM algorithm ([Amelio and Pizzuti, 2014a](#)). Nodes of the graph correspond to image pixels and edges link the most similar image pixels within a spatial neighborhood in the image plan. The similarity is computed according to the brightness difference between the pixels. The fitness function is an extension of the normalized cut criterion, which does not require to prior set the number of clusters. The algorithm has been extended as C-GeNCut (Color-Genetic NCut) in order to include the contribution of color and texture in the similarity computation ([Amelio and Pizzuti, 2013a](#)). Finally, Ref. [Amelio and Pizzuti \(2014b\)](#) introduced GA-IC (Genetic Algorithms Image Clustering), which is a graph-based approach using a genetic algorithm for partitioning an image database. Each node of the graph is an image, while edges link the most similar images. Then, a genetic algorithm is applied on the graph for detecting the node communities which optimize the modularity function. Accordingly, the number of clusters is not an input parameter. The algorithm has been extended as GA-ICDA (Genetic Algorithms Image Clustering for Document Analysis) for partitioning document image databases by introducing the concept of spatial distance between the documents, a final step of clustering refinement, a generalization of the similarity measure, and a procedure for managing singleton clusters. In particular, it has been used for partitioning documents in different languages ([Brodić et al., 2016b](#)), in closely related languages ([Brodić et al., 2015](#)) and in evolving languages ([Brodić et al., 2017](#)). GA-ICDA has been also employed for partitioning documents given in different scripts of the same language ([Brodić et al., 2016a](#)), and in multiple languages and scripts [Brodić et al. \(2016c\)](#). Image and document clustering are two broad research areas which are out the scope of this article. Consequently, we refer to [Anastasiu et al. \(2013\)](#) and [Oikonomakou and Vazirgiannis \(2010\)](#) for further details about document clustering, and to [Ahmed \(2015\)](#) for further details about image clustering.

Semi-structured data clustering. The semi-structured data are typically modeled as tree data. In the last years, it has contributed to the development of different clustering methods for mining the XML data. In particular, Ref. [Costa et al. \(2004\)](#) has proposed a new approach for clustering XML documents, which is based on XML cluster representatives. They are XML documents providing the structural characteristics of a set of XML documents. Clustering is performed by comparison and modification of the cluster representatives as new clusters are found. In [De Meo et al. \(2005\)](#), an approach for clustering heterogeneous XML schema has been proposed. It evaluates the dissimilarity among XML schema by considering interschema semantic properties existing between concepts and builds the dissimilarity matrix to be used by a clustering algorithm. Also, Ref. [Lee et al. \(2002\)](#) has introduced a method for clustering Document Type Definitions (DTD) of XML sources. Semantically and structurally similar DTDs are grouped in the same clusters. Similarity considers not only the linguistic and structural information of the elements in the DTDs, but also the ancestors and descendants of the elements in the DTD trees. Finally, Ref. [Tagarelli and Greco \(2010\)](#) has proposed *SemXClust*, a new method for clustering semantically related XML documents according to their content and structure. XML documents are represented by tree tuples, which are semantically cohesive substructures of the documents represented as XML transactions. Then, two clustering algorithms are proposed to be applied on the XML transactions for clusters detection. An overview of the most recent trends in XML data mining can be found in [Tagarelli \(2011\)](#).

Applications of Data Clustering

Traditional clustering algorithms have been employed in multiple domains as a valid support for detecting classes of data in different contexts, including: (i) image processing, (ii) text mining, (iii) sensor data, (iv) web applications, (v) medical data, and (vi) natural language processing.

Image processing. In image processing, the K-Means algorithm has been used for solving the image segmentation problem, where each pixel is considered as a data point, characterized by color, texture and/or shape features. The algorithm finds groups of pixels corresponding to image regions ([Dhanachandra et al., 2015](#)). Also, Ref. ([Krishnamachari and Abdel-Mottaleb, 1999](#)) has applied an agglomerative hierarchical approach for clustering image collections according to the image content. Users can browse the hierarchy of images by scanning the obtained dendrogram. The Blobworld image retrieval system has applied the EM algorithm for dividing the image pixels into regions which can be used for retrieving similar images from an image query ([Carson et al., 2002](#)).

Text mining. In the text and document mining context, Ref. Wang *et al.* (2011) has applied an agglomerative hierarchical approach for clustering collections of text documents. Clustering is performed on a graph where the nodes are the words representing a description of the documents, and the edges are the relationships between the words. Also, in Bide and Shedge (2015) the K-Means algorithm has been used for clustering a collection of documents by following a Divide and Conquer strategy which divides the documents in smaller groups. Still, Ref. Li and Huang (2010) has analyzed the ability of K-Medoid and DBSCAN algorithms in clustering collections of text documents according to their content. Results demonstrate that DBSCAN performs considerably better than K-Medoid which is sensitive to the initial setting of the centroids. In Sarnovsky and Carnoka (2016), a distributed K-Means algorithm using Jbowl text mining library and GridGain framework has been designed and implemented for clustering collections of text documents.

Sensor data. Clustering has also been adopted for partitioning data generated by instrumentation measuring physical quantities. In Brodić and Amelio (2015), the K-Means algorithm has been applied on magnetic field data measured in the neighborhood of the laptop computers in order to detect the emission levels to which the laptop's users are exposed. The experiment has been extended to cases when the laptop is overloaded with heavy applications (under stress condition) Brodić and Amelio (2016). A similar experiment has been performed on magnetic field data measured in the neighborhood of the laptop's AC adapters for detecting their emission levels Brodić and Amelio (2017). In the same context, the SOM algorithm has been employed for evaluating the ability of an artificial neural network model in predicting the magnetic field levels from known laptop characteristics (Brodić *et al.*, 2016).

Web applications. In the web context, the K-Means algorithm has been used for clustering the search results in order to improve the browsing of the content Poomagal and Hamsapriya (2011). The web documents obtained by the search are partitioned into clusters according to the extracted words and their frequency. Also Ref. de Paiva and Costa (2012) has proposed the application of the SOM algorithm to web log files in order to detect the similarities between users' sessions. It has the aim to identify users presenting similar interests in order to create personalized navigation environments. In Morichetta *et al.* (2016), the DBSCAN has been employed for clustering the web URLs in order to identify suspicious traffic on the web.

Medical data. Clustering in the medical context has been used for supporting the diagnosis process. In particular, Ref. Albayrak (2003) has experimented the application of K-Means and SOM algorithms on thyroid gland data, in order to detect normal, hyperthyroid and hypothyroid functions. Also, in Amelio and Pizzuti (2013b) the C-GeNCut algorithm has been applied on dermatological image repositories for the extraction of skin lesions from the background, e.g. melanoma images. In Sharan and Shamir (2000), the CLICK algorithm has been used in the biological field for clustering genes in groups with similar expression patterns.

Natural language processing. In natural language processing, an approach for building a multilingual web directory based on the application of SOM algorithm has been introduced (Yang *et al.*, 2011). A network is used for learning each set of monolingual web pages. Then, a hierarchy generation and alignment process is applied on the networks to build the final multilingual hierarchy. Also, Ref. Kumar *et al.* (2011) has proposed the application of the bisecting K-Means for clustering multilingual documents according to the document similarities, where linguistic elements from Wikipedia are used for improving the document representation.

Analysis and Assessment

Different criteria have been introduced for evaluating the quality of a clustering solution. In particular, they can be divided in two main categories: (i) internal criteria, and (ii) external criteria (Béjar, n.d.). Internal criteria evaluate the clustering according to the quality of the partition. External criteria compare the clustering solution with the labeled data, also called ground-truth partitioning. In the following, we describe some criteria belonging to each category. Other evaluation criteria are described and analyzed in Halkidi *et al.* (2001).

Internal Criteria

Three known internal criteria for clustering evaluation are: (i) Silhouette coefficient, (ii) Davies-Bouldin index, and (iii) Ball-Hall index.

The Silhouette coefficient evaluates the clustering quality in terms of separation between the clusters and cohesion inside the clusters. For the i -th data point, it computes its average distance with the other data points in its cluster. It is denoted as a_i . Then, for any other cluster, it computes the average distance with its data points and finds the minimum distance over the clusters. It is denoted as b_i . Accordingly, the Silhouette coefficient is defined as follows (Desgraupes, n.d.):

$$s_i = \frac{b_i - a_i}{\max(a_i, b_i)} \quad (13)$$

The value of the Silhouette coefficient ranges between -1 ($a_i > b_i$, worst case) and 1 ($a_i = 0$, best case).

The Davies-Bouldin index quantifies the average similarity between each cluster and its most similar cluster. Because a better solution corresponds to cohesive and well-separated clusters, a lower index value indicates a better clustering. In particular, let δ_k be the average distance between the data points belonging to cluster c_k and its centroid m_k :

$$\delta_k = \frac{1}{n_k} \sum_{i=1}^{n_k} \|x_i^{(k)} - m_k\| \quad (14)$$

Also, let $\Delta_{kk'}$ be the distance between the centroids m_k and $m_{k'}$ of the clusters c_k and $c_{k'}$:

$$\Delta_{kk'} = \|m_k - m_{k'}\| \quad (15)$$

The Davis-Bouldin index is defined as (Desgraupes, n.d.):

$$\mathcal{D} = \frac{1}{K} \sum_{k=1}^K \max_{k' \neq k} \left(\frac{\delta_k + \delta_{k'}}{\Delta_{kk'}} \right) \quad (16)$$

The Ball-Hall index is the average of the squared distances between the data points of each cluster and its centroid (Desgraupes, n.d.). It is defined as follows:

$$\mathcal{B} = \frac{1}{K} \sum_{k=1}^K \frac{1}{n_k} \sum_{i=1}^{n_k} \|x_i^{(k)} - m_k\|^2 \quad (17)$$

External Criteria

Three external criteria for clustering evaluation are: (i) Normalized Mutual Information, (ii) Adjusted Rand Index, and (iii) Jaccard index.

Let $C = \{c_1, c_2, \dots, c_K\}$ be a clustering solution composed of K clusters, and $P = \{p_1, p_2, \dots, p_K\}$ be the ground-truth partitioning in clusters. The overlap between C and P can be represented by the contingency table CM shown in Table 2 (Yeung and Ruzzo, n.d.):

According to the contingency table CM , the Normalized Mutual Information (NMI) can be computed as follows:

$$NMI = \frac{\sum_{ij} n_{ij} \log \frac{M n_{ij}}{n_i n_j}}{\sqrt{\left(\sum_i n_i \log \frac{n_i}{M} \right) \left(\sum_j n_j \log \frac{n_j}{M} \right)}} \quad (18)$$

where M is the total number of data points. The NMI is bounded between 0 (perfect mismatch) and 1 (perfect match). It represents the amount of information given by the clusters and useful to derive the membership of the data points in the ground-truth clusters (Vinh et al., 2010). The main limitation of this measure is the selection bias problem, which is the tendency to obtain higher values for clustering solutions with many clusters. Recently, an adjustment of the NMI has been introduced, which scales the value of the NMI by a scaling factor. It is computationally not expensive and avoids the selection bias problem by penalizing the clustering solutions with a very low or very high number of clusters (Amelio and Pizzuti, 2016).

Other measures compare C and P according to the pairs of data points which are in the same or different clusters. In particular, the Adjusted Rand Index (ARI) is defined as (Yeung and Ruzzo, n.d.):

$$ARI = \frac{\sum_{ij} \binom{n_{ij}}{2} - \left[\sum_i \binom{a_i}{2} \sum_j \binom{b_j}{2} \right] / \binom{n}{2}}{\frac{1}{2} \left[\sum_i \binom{a_i}{2} + \sum_j \binom{b_j}{2} \right] - \left[\sum_i \binom{a_i}{2} \sum_j \binom{b_j}{2} \right] / \binom{n}{2}} \quad (19)$$

It varies between -1 and 1 , and takes 0 for random partitioning and 1 for perfect agreement.

Finally, the Jaccard index is similar to ARI, with the difference that it does not consider the pairs of data points which are in different clusters. The Jaccard index is the following (Wagner and Wagner, n.d.):

$$\mathcal{J} = \frac{n_{11}}{n_{11} + n_{10} + n_{01}} \quad (20)$$

where n_{11} is the number of pairs which are in the same cluster in C and P , n_{10} is the number of pairs which are in the same cluster in C and in different clusters in P , and n_{01} is the number of pairs which are in different clusters in C and in the same cluster in P .

Table 2 Contingency table CM

C/P	p_1	p_2	...	p_K	Sums
c_1	n_{11}	n_{12}	...	n_{1K}	a_1
c_2	n_{21}	n_{22}	...	n_{2K}	a_2
...	...	...	...	...	...
c_K	n_{K1}	n_{K2}	...	n_{KK}	a_K
Sums	b_1	b_2	...	b_K

Closing Remarks

Clustering is the procedure of partitioning data into homogeneous groups such that data belonging to the same group are similar and data belonging to different groups are dissimilar. This article presented the main elements characterizing the clustering problem. It was realized by describing the most common measures for similarity or distance evaluation in a clustering approach, the most relevant clustering methodologies, and some important criteria for assessing the clustering solution. In particular, two broad categories of clustering approaches, partitional and hierarchical, were described. Also, density-based clustering approaches were discussed. Finally, some clustering approaches specifically designed for non-conventional data were presented. The focus of this work was on the methodological aspects of clustering, with a section dedicated to some application cases which contextualize the methodology. It can be of particular interest to students who approach for the first time to the clustering problem, as well as scientists, in academia and research institutes, as a valid support for designing new clustering methods advancing the proposed clustering methodologies in the state-of-the-art.

Biographical Sketch

Alessia Amelio received her BSc and MSc magna cum laude in Computer Science Engineering from University of Calabria in 2005 and 2009, as well as Ph.D. in computer science engineering and systems from the Faculty of Engineering, University of Calabria in 2013. During her Ph.D., she was visiting research scholar at College of Computing, Georgia Institute of Technology, under the supervision of prof. Alberto Apostolico. From 2011 to 2014 she was research fellow at the National Research Council of Italy. From 2015 to 2016 she was researcher at the National Research Council of Italy. Now she is research fellow of computer science at the Department of Computer Science Engineering, Modeling, Electronics and Systems, University of Calabria, Italy. Her current research interests include different aspects of image processing, document classification, pattern recognition from sensor data, social network analysis, data mining and artificial intelligence methods for the web. She co-authored more than 20 journal papers indexed in Scopus and Web of Science, and more than 40 conference papers, book chapters and magazine papers. She was chair and co-organizer of two invited sessions as well as session chair in different international conferences. She has also served as a reviewer as well as a member of program committee for leading journals and conferences in the fields of data mining, knowledge and data engineering, artificial intelligence, and physics.

Andrea Tagarelli is an assistant professor of computer engineering at the University of Calabria, Italy. He graduated magna cum laude in computer engineering, in 2001, and obtained his Ph.D. in computer and systems engineering, in 2006. He was research fellow at the Department of Computer Science & Engineering, University of Minnesota at Minneapolis, United States, working in the George Karypis's Data Mining Lab, in 2007. In 2013, he obtained the Italian national scientific qualification to associate professor, and in 2017 the qualification to full professor, for the computer science and engineering research area (scientific disciplinary sector ING-INF/05). His research interests include topics in data mining, web and network science, information retrieval, artificial intelligence. On these topics, he has coauthored more than 100 peer-reviewed papers, including journal articles, conference papers and book chapters. He also edited a book titled XML Data Mining: Models, Methods, and Applications. He was co-organizer of three workshops and a mini-symposium on data clustering topics in premier conferences in the field (ACM SIGKDD, SIAM DM, PAKDD, ECML-PKDD). He has also served as a reviewer as well as a member of program committee for leading journals and conferences in the fields of databases and data mining, knowledge and data engineering, network analysis, information systems, knowledge based systems, and artificial intelligence. Since 2015, he has been in the editorial board of Computational Intelligence Journal and Social Network Analysis and Mining Journal.

Computation Cluster Validation in the Big Data Era

Raffaele Giancarlo, University of Palermo, Palermo, Italy

Filippo Utro, IBM Thomas J. Watson Research Center, Yorktown Heights, NY, United States

© 2019 Elsevier Inc. All rights reserved.

Introduction

One of the main tasks of exploratory data analysis, and a common practice in statistics, is the grouping of items in a set in such a way that items in the same group (called a cluster) are more similar to each other than to those in other clusters.

The most fundamental issue to be addressed when clustering data consists of the determination of the number of clusters. Related issues are how to assign confidence levels to the selected number of clusters, as well as to the induced cluster assignments. Those issues are particularly important in data analysis and become quite difficult when the data available offer a relatively small sample size and are of very high dimensionality, making the clustering results especially sensitive to noise and susceptible to overfitting. Many data of interest to the Life Sciences exhibit those features, for example, microarrays.

In this article, we start by giving a formal definition of the basic issues concerning cluster analysis. Then, we present some related notions from Hypothesis Testing in Statistics.

Finally, we present a case study on microarray data, trying to answer to two fundamental questions: (1) What is the precision of a method, i.e., its ability to predict the correct number of clusters in a dataset? (2) Among a collection of methods, which is more accurate, less algorithm dependent, etc.?

It is to be remarked that although some of the methodologies described here have been validated only on biological data, namely microarrays, they are generic in the sense that they can be applied to any kind of data. Moreover, it is relevant to mention here that recently they are becoming quite popular in domains other than microarray data analysis (e.g., [Giroto et al. \(2016\)](#), [McMurdie and Holmes \(2013\)](#), and [Utro et al. \(2012\)](#)).

Background

The aim of cluster analysis is to divide data into groups (i.e., clusters) that are meaningful and lead to significant insights about the data. The partition of the data into clusters is based on information present in the data itself. Formally, consider a set of n items $(\Sigma) = \{\sigma_1, \dots, \sigma_n\}$, where σ_i is specified by m numeric values, referred to as features or conditions, for each integer $i \in [1, n]$. That is, each σ_i is an element in m -dimensional space. Let $C_k = \{c_1, c_2, \dots, c_k\}$ be a partition of (Σ) into k clusters, i.e., a set of subsets of (Σ) such that $\cup_{i=1}^k c_i = (\Sigma)$ and $c_i \cap c_j = \emptyset$ for $1 \leq i \neq j \leq k$. Each subset c_i , where $1 \leq i \leq k$, is referred to as a cluster, and C_k is referred to as a clustering solution. The aim of cluster analysis is to determine a partition of (Σ) according to a similarity/distance S , which is referred to as similarity/distance metric. It is defined on the elements in (Σ) . In particular, one wants that items in the same cluster to have “maximal similarity”, while items in different clusters are “dissimilar”. Typically, (Σ) is represented in one of two different ways: (1) a data matrix D , of size $n \times m$, in which the rows represent the items and the columns represent the feature values; (2) a similarity/dissimilarity matrix S , of size $n \times n$, in which each entry S_{ij} , with $1 \leq i \neq j \leq n$, is the value of similarity/dissimilarity of σ_i and σ_j . Particularly, the value of S_{ij} can be computed using rows i and j of D . Hence, S can be derived from D , but not vice versa. The specification and formalization of a similarity metric, via mathematical functions, depends heavily on the application domain and it is one of the key steps in clustering, in particular in the case of biological data (e.g., microarray). The state of the art, as well as some relevant progress in the identification of good distance functions for microarrays, is presented in [Giancarlo et al. \(2013\)](#), [Sera et al. \(2016\)](#) and references therein.

Typically, the partition of (Σ) into groups is accomplished via a clustering algorithm A . A classical classification of clustering algorithms is hierarchical versus partitional. The hierarchical clustering algorithms produce a nested sequence of partitions ([Jain and Dubes, 1988](#)). The partitional clustering algorithms directly decompose the dataset into a partition C_k . In this article, we limit ourselves to the class of clustering algorithms that take in input D and an integer k and return C_k .

Assessment of Cluster Quality: Main Problems Statement

Assume that one is given a set of genes. Then, a sensible biological question would be to find out how many functional groups of genes are present in a dataset. Since the presence of “statistically significant patterns” in the data is usually an indication of their biological relevance ([Leung et al., 1996](#)), it makes sense to ask whether a division of the items into groups is statistically significant. In what follows, the three problem statements in which that question can be cast ([Jain and Dubes, 1988](#)) are detailed. Let $\bar{C}_j$ be a reference classification for (Σ) consisting of j classes. That is, $\bar{C}_j$ may either be a partition of (Σ) into j groups, usually referred to as the gold standard, or a division of the universe generating (Σ) into j categories, usually referred to as class labels. An external index E is a function that takes as input a reference classification $\bar{C}_j$ for (Σ) and a partition C_k of (Σ) and returns a value assessing how close the partition is to the reference classification. It is external because the quality assessment of the partition is established via criteria external to the data, i.e., the reference classification. Notice that it is not required that $j=k$. An internal index I is a function defined

on the set of all possible partitions of (Σ) and with values in $\mathbb{R}$. It should measure the quality of a partition according to some suitable criteria. It is internal because the quality of the partition is measured according to information contained in the dataset without resorting to external knowledge. The first two problems are:

- (a) Given $\bar{C}_j$, C_k and E , measure how far is C_k from C_{k^*} according to E . That is, we are examining if k is the number of clusters one expects in D .
- (b) Given C_k and I , establish whether the value of I computed on C_k is unusual and therefore surprising. That is, significantly small or large.

We observe that these two problems try to assess the quality/goodness of a clustering solution C_k consisting of k groups, but give no indication whether k is the “right number” of clusters. In order to get such an indication, we are interested in the following:

- (c) Assume we are given: (a) A sequence of clustering solutions $C_1, \dots, C_s$, obtained for instance via repeated application of a clustering algorithm A ; (b) a function R , usually referred to as a relative index that estimates the relative merits of a set of clustering solutions. We are interested in identifying the partition C_{k^*} among the ones given in (a) providing the best value of R . Let k^* be the optimal number of clusters according to R .

The clustering literature is extremely rich in mathematical functions suited for the three problems outlined above (Handl et al., 2005). The crux of the matter is to establish quantitatively the threshold values allowing us to say that the value of an index is significant enough. That naturally brings us to briefly mention Hypothesis Testing in Statistics, from which one can develop methods to assess the statistical significance of an index.

Assessment of Cluster Significance: A Generic Procedure

A statistic T is a function that captures helpful information about the data, i.e., it can be one of the indices mentioned earlier. Formally, it is a random variable and its distribution describes the relative frequency with which values of T occur, on which, one implicitly assumes that there is a background/reference probability distribution for its values. That implies the existence of a sample space. A hypothesis is a statement about the frequency of events in the sample space. It is tested by observing a value of T and by deciding how unusual it is, according to the probability distribution one is assuming for the sample space. The most common hypothesis tested for in clustering is the null hypothesis, H_0 : *there is no structure in the data* (i.e., $k=1$). Testing for H_0 with a statistic T in a dataset D means to compute T on D and then decide whether to reject or not H_0 . Therefore, one needs to establish how significant is the value found with respect to a background probability distribution of the statistic T under H_0 via a formalization of the notion of “no structure” or “randomness” in the data. Among the many possible ways, commonly indicated to as null models, the most relevant proposed in the clustering literature are detailed in Bock (1985), Gordon (1996), Jain and Dubes (1988), and Sarle (1983).

After a null model has been selected, one would need to gain formulas giving the value of T under the null model and for a specific set of parameters. Disappointingly, since not too many such formulae exist, one typically resorts to a Monte Carlo simulation applied to the context of assessing the significance of C_k .

We anticipate that Section Internal indices provides methods that resort to the same principles and guidelines mentioned above, although they are more specific about the statistic that is relevant to identify the number of clusters in a dataset.

Fundamental Validation Indices

In this section, some essential validation methods are introduced. In particular, external and internal indices are outlined. In the literature concerning this topic, the terms index and measure are interchangeable. The external and internal indices differ fundamentally in their aims, and find application in distinct experimental settings. Recalling the previous section, external indices can be used to validate clustering algorithms, while internal measures can be used as data driven techniques to estimate the number of cluster in a data set.

We start by presenting three external indices that assess the agreement between two partitions. Then, we present the most prominent internal measures useful to estimate the correct number of clusters present in a dataset, and that fall into one of the following paradigms: (1) compactness (2) hypothesis testing in statistics; (3) stability-based techniques and (4) jackknife techniques.

External indices

As already mentioned, an external measure is a function that takes as input two partitions C_j and C_k and returns a value assessing how close C_k is to C_j . It is external because the quality assessment of the partition is established via criteria external to the data. Notice that it is not required that $j=k$. Three most prominent external measures known in the literature are: the Adjusted Rand Index (Hubert and Arabi, 1985), the F-index (Van Rijsbergen, 1979) and the Fowlkes and Mallows Index (Fowlkes and Mallows, 1983). All three can be computed via a contingency table described below, however, for brevity only the Adjusted Rand Index is considered here.

Given two partitions $\bar{C}_r$ and C_{k^*} with the notation of Section Assessment of Cluster Quality: Main Problems Statement, $\bar{C}_r$ is an external partition of the items, derived from the reference classification, while C_{k^*} is a partition obtained by some clustering

method. Let $n_{i,j}$ be the number of items in both $\bar{c}_i$ and c_j , $1 \leq i \leq r$ and $1 \leq j \leq t$. Moreover, let $|\bar{c}_i| = n_{i,*}$ and $|c_j| = n_{*,j}$. Those values can be conveniently arranged in a contingency table:

Class/Cluster	c_1	c_2	...	c_k	Sums
$\bar{c}_1$	$n_{1,1}$	$n_{1,2}$	...	$n_{1,k}$	$n_{1,*}$
$\bar{c}_2$	$n_{2,1}$	$n_{2,2}$	...	$n_{2,k}$	$n_{2,*}$
...	...	...	...	...	...
$\bar{c}_r$	$n_{r,1}$	$n_{r,2}$	...	$n_{r,k}$	$n_{r,*}$
Sums	$n_{*,1}$	$n_{*,2}$	...	$n_{*,k}$	$n_{*,*} = n$

Adjusted Rand Index R_A is derived from a generalization of a hypergeometric distribution as the null hypothesis. That is, it is assumed that the row and column sums in the contingency table are fixed, but the two partitions are picked at random. Formally, it is defined as:

$$R_A = \frac{\sum_{i,j} \binom{n_{i,j}}{2} - \frac{\sum_i \binom{n_{i,*}}{2} \sum_j \binom{n_{*,j}}{2}}{\binom{n}{2}}}{\frac{1}{2} \left[\sum_i \binom{n_{i,*}}{2} + \sum_j \binom{n_{*,j}}{2} \right] - \frac{\sum_i \binom{n_{i,*}}{2} \sum_j \binom{n_{*,j}}{2}}{\binom{n}{2}}}$$

R_A assumes values in the interval $[-\infty, 1]$. It assumes value one, when there is a perfect agreement between the two partitions, while its expected value of zero indicates a level of agreement due to chance. Therefore, the two partitions are in significant agreement if R_A assumes a non-negative value, substantially away from zero.

Internal indices

Internal indices assess the quality of a partition, without any use of external information. Then, a Monte Carlo simulation can determine if the value of such an index on the given partition is unusual enough for the user to gain confidence that the partition is good. Internal indices are also an essential building block in order to obtain relative indices that support to select, among a given set of partitions, the “best” one. For the state of the art on internal measures, the reader is referred to [Giancarlo et al. \(2008\)](#), [Handl et al. \(2005\)](#), and [Giancarlo and Utró \(2012\)](#). Some of the most prominent internal measures are based on: (1) compactness (2) hypothesis testing in statistics; (3) stability-based techniques and (4) jackknife techniques.

This also gives a natural division of the most prominent measures in the literature:

- Within Clusters Sum of Square (WCSS for short) ([Hastie et al., 2003](#)) and Krzanowski and Lai Index (KL for short) ([Krzanowski and Lai, 1985](#)).
- Gap Statistics (Gap for short) ([Tibshirani et al., 2001](#)).
- CLEST ([Dudoit and Fridlyand, 2002](#)), Model Explorer (ME for short) ([Ben-Hur et al., 2002](#)), Consensus Clustering (Consensus for short) ([Monti et al., 2003](#)).
- Figure of Merit (FOM for short) ([Yeung et al., 2001](#)).

We are selecting only one internal measure from each of the mentioned classes and highlight here a few key facts about them, referring the interested reader to [Giancarlo et al. \(2008\)](#) for a more in-depth presentation of each of the measures, as well as additional references to textbooks and papers covering additional aspects of those measures.

WCSS measures the “goodness” of a cluster solution via its compactness, one of the most fundamental indicators of cluster quality. Indeed, for each $k \in [1, k_{\max}]$, the method consists of computing the sum of the square distance between each element in a cluster and the centroid of that cluster. The “correct” number of clusters k^* is predicted according to the following rule of thumb. For each $k < k^*$, the value of WCSS should be substantially decreasing, as a function of the number of clusters k . On the other hand, for values of $k^* < k$, the compactness of the clusters will not increase as much, causing the value of WCSS not to decrease as much. The following heuristic approach comes out ([Hastie et al., 2003](#)): Plot the values of WCSS, computed on the given clustering solutions, in the range $k \in [1, k_{\max}]$; choose as k^* the abscissa closest to the *knee* in the WCSS curve.

Gap is one of the few measure that incarnates the Monte Carlo Confidence Analysis paradigm. It is based on WCSS. In particular, via a Monte Carlo simulation it tries to identify the knee in the WCSS curve. Intuitively, a null model is generated for each $k \in [1, k_{\max}]$, the “distance” (i.e., gap) between the null model and the WCSS curve is computed. Therefore, it returns as k^* the first value of k such that its gap is less than the its value at $k+1$ corrected by the standard deviation accounting for the null model.

Consensus builds, for each $k \in [2, k_{\max}]$, a consensus matrix indicating the level of agreement of clustering solutions, via a series of independent sampling of the dataset and their partitions via a clustering algorithm. Based on experimental observations and logic arguments, [Monti et al. \(2003\)](#) derived a *rule of thumb* to estimate k^* based on the empirical cumulative distribution function of the entries of the consensus matrix. The interested reader is referred to [Monti et al. \(2003\)](#) for details.

FOM is based on a root mean square deviation over all features. It uses the same heuristic methodology outlined for WCSS, i.e., one tries to identify the knee in the *FOM* plot as a function of the number of clusters.

It is worth pointing out that also some heuristics have been proposed in the literature to gain a speed-up of some of the mentioned measures, keeping at the same time good performance in term of the assessment of k^* . The interested reader is referred to [Giancarlo et al. \(2008\)](#) and [Giancarlo and Utro \(2011, 2012\)](#).

A Case Study on Microarray Data

In the remainder of this section, the experimental framework used in this manuscript is detailed, i.e., datasets, algorithms and hardware. The intention is not only to analyze the performance of each measure in term of its ability to estimate k^* , but to also account for the computational resources it needs for that task.

It is useful to recall the definition of “gold solution” that naturally yields a partition of the datasets in two main categories. Strictly speaking, a gold solution for a dataset is a partition of the data in a number of classes known *a priori*. For their extensive benchmarking, [Giancarlo et al. \(2008\)](#) and [Giancarlo and Utro \(2011\)](#) used several datasets with a gold solution. For the sake of conciseness, only one of their datasets is used in this article.

Lymphoma: It is an 80×100 data matrix, where each row corresponds to a tissue sample and each column to a gene. The dataset comes from the study of [Alizadeh et al. \(2000\)](#) on the three most common adult lymphoma tumors. There is a partition into three classes and it is taken as the gold solution. The dataset has been obtained from the original microarray experiments, consisting of an 80×4682 data matrix, following the same preprocessing steps detailed in [Dudoit and Fridlyand \(2002\)](#).

Clustering Algorithm

In this article, a suite of clustering algorithms is used. Among the hierarchical methods ([Jain and Dubes, 1988](#)) Hier-A (Average Link), Hier-C (Complete Link), and Hier-S (Single Link), are used. Moreover, K-means ([Jain and Dubes, 1988](#)) is used, both in the version that starts the clustering from a random partition of the data and in the version where it takes, as part of its input, an initial partition produced by one of the chosen hierarchical methods. For K-means, the acronyms of those versions are K-means-R, K-means-A, K-means-C and K-means-S, respectively. All of the algorithms use Euclidean distance in order to assess similarity of single elements to be clustered.

Hardware, Tools and Availability

All experiments for the assessment of the precision and timing were performed on a MacBook Pro (Retina, 15-in., Mid 2015), with 2.5 GHz Intel Core i7 processor and 16 GB of memory. All measures are implemented in ValWorkBench ([Giancarlo et al., 2015](#)) and see Section Relevant Website.

Analysis and Assessment

In this section, we are assessing the ability of the clustering algorithms as well as the performance of the internal validation measures.

Clustering Algorithms

External indices can be very useful in evaluating the performance of algorithms and internal/relative indices, with the use of datasets that have a gold standard solution. A brief illustration is given of the methodology for the external validation of a clustering algorithm, via an external index that needs to be maximized. The same methodology applies to internal/relative indices, as discussed in [Yeung et al. \(2001\)](#). For a given dataset, one plots the values of the index computed by the algorithm as a function of k , the number of clusters. Then, one expects the curve to grow to reach its maximum close or at the number of classes in the reference classification of the dataset. After that number, the curve should fall. In what follows, the results of the experiments are presented, with the use of the indices. For each dataset and each clustering algorithm, the *Adjusted Rand Index* computed for a number of cluster values in the range $[2,30]$ (see [Fig. 1](#)). The performance of the algorithms is somewhat mixed, and sometimes they are not precise, for example, the Hier-S algorithm.

The interested reader is referred to [Giancarlo and Utro \(2011\)](#) for a complete analysis of the other indices and datasets.

Internal Validation Measures

All internal validation measures mentioned in Section Background, in conjunction with any of the clustering algorithms detailed in Section A Case Study on Microarray Data have been used to estimate the number of cluster in the Lymphoma dataset. For brevity, we report in [Table 1](#) only the results for each method in conjunction with Hier-A, while the interested reader is referred to [Giancarlo et al. \(2008\)](#) for the complete list of experiment results.

Fig. 1 The *Adjusted Rand Index* curves, for the Lymphoma datasets, as a function of the number of clusters, is plotted differently for each algorithm.

Table 1 A summary of the results of the Hier-A on all methods for the Lymphoma dataset. The columns precision indicates the number of clusters predicted by the measure, while the other one reports the timing in seconds for the execution of the corresponding experiment

	Precision	Timing (s)
WCSS-Hier-A	6	4.0×10^{-1}
Gap-Hier-A	6	5.6×10^0
Consensus-Hier-A	3	3.8×10^2
FOM-Hier-A	6	9.7×10^{-1}
Gold Solution	3	—

Results and Discussion

As it self evident from the results in Section Internal Validation Measures, and the broader results reported in [Giancarlo et al. \(2008\)](#), [Giancarlo and Utro \(2011\)](#), when computational time is taken into account, there is a hierarchy of measures, with WCSS being the fastest and *Consensus* the slowest. Overall, *Consensus* results to be the method of choice in terms of predictive power. From the experiments reported in [Giancarlo et al. \(2008\)](#) and [Giancarlo and Utro \(2011\)](#) *FOM* is the second best performer, although it may not be competitive since it has essentially the same predictive power of WCSS but it is much slower in time, depending on the dataset. Moreover, it is worth recalling that some approximation/heuristics of the mentioned measures have been proposed ([Giancarlo et al., 2008](#); [Giancarlo and Utro, 2011](#)) and that some of them seem quite competitive due to their precision and computational efficiency.

Finally, it is worth pointing out that all the measures we have considered show severe limitations on large datasets, either due to computational demand or to lack of precision.

Future Directions

Some possible future directions involve the design of fast approximations of other stability internal validation measures. It would be a quite remarkable accomplishment to design an internal validation measure that closes the gap between the time performance

of the fastest internal validation measures and the most precise. Moreover, high performance computing, i.e., shared memory multi-thread (Unold and Tagowski, 2015) may be also explored to improve the performance of validation measures.

Closing Remarks

We have provided a tutorial on techniques with grounds in the statistics literature and that are of use for (1) partitioning and (2) estimating the number of clusters in a data set. We have also demonstrated some of their uses on real case studies. It is worth pointing out that the analysis of microarray data, as all types of biological data, offers unique challenges due to their level of noise and their high-dimensionality.

Biographical Sketch

Raffaele Giancarlo is a Full Professor of Computer Science at University of Palermo. His research interests include Algorithms and Data Structures, Data Compression, Information Retrieval, Bioinformatics and Computational Biology. He has produced over 100 research papers in distinguished journals and international conferences. He holds 5 patents.

Dr. Filippo Utro is a Research Scientist in the Computational Genomics group at the IBM T.J. Watson Research Center. He joined IBM Research in 2011 after completing his PhD work in computer science at the University of Palermo, Italy. His research is focused around algorithm development and analysis, specifically on challenges in computational biology. He started his career at IBM as an investigator in the cacao genome project and has since continued to research on plant, population, epigenetics and cancer genomics. He has produced over 30 research papers in distinguished journals and international conferences, and holds 5 patents (pending).

Data Mining: Outlier Detection

Fabrizio Angiulli, University of Calabria, Rende, Italy

© 2019 Elsevier Inc. All rights reserved.

Outlier Detection

Outlier detection is one of the prominent data mining tasks, with a lot of applications in several domains. While the other three main data mining tasks, that are clustering, classification, and dependency detection, deal with regularities in the data, the goal of outlier detection is to isolate anomalous observations within the data. Clustering is the process of partitioning a set of objects into homogeneous groups, or clusters. Classification is the task of assigning objects to one of several predefined categories. Dependency detection techniques search for pairs of attribute sets which exhibit some degree of correlation in the dataset at hand.

As for the outlier detection task, it can be defined as follows: given a set of data points or objects, find the objects that are considerably dissimilar, exceptional or inconsistent with respect to the remaining data. These exceptional objects are also referred to in the literature as outliers.

It must be noticed that the other three categories of data mining techniques also deal with outliers, since many clustering, classification and dependency detection methods produce outliers as a by-product of their main task. Indeed, mislabeled points are considered outliers by classification techniques and they should be removed from the training set to improve the accuracy of the learned classifier. Also, points that do not well fit to any cluster are considered outliers by clustering techniques.

Despite these techniques can be able to treat some form of anomalies, it must be pointed out that the approach of searching for outliers through techniques which are not explicitly designed for detecting outliers presents different drawbacks. To illustrate, the quality of clusters returned by a clustering algorithm is usually affected by the presence of outliers and this in its turn affects the quality of the associated by-product outliers.

The advantage of outlier detection definitions relies on the fact that they are tailored on specific notions of abnormality. Moreover, other than guaranteeing an higher quality, outlier detection algorithms can be enormously more efficient than algorithms searching for regularities.

In the context of regularity-based data mining tasks, outliers are considered as noise that must be eliminated since they worsen the predictive or descriptive capabilities of algorithms. However, as already pointed in the literature, one person's noise could be another person's signal, and thus there are applications in which the outliers themselves represent the knowledge of interest. Outlier mining is used in telecom or credit card frauds, in intrusion detection, in medical analysis, in marketing and customer segmentation, in surveillance systems, in data cleaning, in biological data analysis and in many other fields.

Outlier Detection Approaches

Approaches to outlier detection can be grouped in three main families: supervised, semi-supervised, and unsupervised ([Aggarwal, 2013](#)).

Supervised methods exploit the availability of a labeled dataset, containing observations already labeled as normal and abnormal, in order to build a model of the normal class. Since usually normal observations are the great majority, these datasets are unbalanced and specific classification techniques must be designed to deal with the presence of rare classes.

Semi-supervised methods assume that only normal examples are given. The goal is to find a description of the data, that is a rule partitioning the point space into an accepting region, containing the normal points, and a rejecting region, containing all the other points. These methods are also called one-class classifiers or domain description techniques, and they are related to novelty detection since the domain description is used to identify points significantly deviating from the training examples.

Unsupervised methods search for outliers in an unlabelled dataset by assigning to each point a score which represents its degree of abnormality. Scores are usually computed by comparing each point with the points belonging to its neighborhood.

Data mining researchers have largely focused on unsupervised approaches. The rest of this section provides a detailed overview of the main unsupervised outlier detection approaches. Each family of approaches is presented in a separate subsection.

Statistical-Based Outliers

Early approaches to detect outliers originated in statistics. [Hawkins' \(1980\)](#) definition of outlier is usually reported to clarify the kind of approach: "An outlier is an observation that deviates so much from other observations as to arouse suspicions that it was generated by a different mechanism". Statistical approaches are model-based, since a model is hypothesized for the data and the points are evaluated with respect to how well they fit the model or generating mechanism: an outlier is a point that has low probability to occur with respect to the probability distribution associated with the data.

Once a distribution model is selected, its parameters are estimated from data, e.g. the mean and the standard deviation for a normal distribution. A lot of statistical tests have been designed in the statistical literature, many of which are highly specialized. In [Barnett and Lewis \(1994\)](#) a comprehensive treatment is provided, listing about one hundred discordancy tests that differ for (*a*)

the distribution, (b) whether or not the distribution parameters are known, (c) the number of expected outliers, (d) the type of outliers, e.g. upper or lower.

For example, in a one-dimensional Gaussian distribution there is little chance that a value x will occur more than c standard deviations σ apart from the mean μ . Thus, given a significance level α , c can be obtained as the value such that

$$\Pr \left[\left| \frac{x - \mu}{\sigma} \right| \geq c \right] \leq \alpha$$

This approach can be generalized to higher dimensions by exploiting the Mahalanobis distance of a point to the mean of the distribution, which is directly related to the probability to observe the point.

When there is knowledge of the data and the kind of test to apply, these tests can be very effective. The problems of statistical tests are that in most cases no standard distribution can adequately model the observed values whose underlying distribution is in most cases unknown, that there may not be a test developed for the case at hand, and that they admit in general only one generating mechanism or cluster.

Distance-Based Outliers

Distance-based outlier detection has been introduced by Knorr *et al.* (2000) to overcome some limitations of statistical methods. According to the definition there provided, an object x is a *distance-based outlier* with respect to parameters k and R if less than k objects in the dataset lie within distance R from x . This definition corresponds to a form of density estimation based on counting the number of data points lying in a fixed-size neighborhood of the point, that is an hypersphere of radius R in the Euclidean space.

Subsequently, Ramaswamy *et al.* (2000) in order to provide a ranking of the outliers, modified the previous definition as follows: given two integers k and n , an object x is said to be the n -th top outlier if exactly $n-1$ objects have higher value for D_k than x , where D_k denotes the distance of the k -th nearest neighbor of the object.

Moreover, Angiulli and Pizzuti (2005) with the aim of taking into account the whole neighborhood of each point, proposed to rank points on the basis of the average distance from their k nearest neighbors, a measure called *weight*, and introduced the *HilOut* (Angiulli and Pizzuti, 2005) and *SolvingSet* algorithms (Angiulli *et al.*, 2006) for their efficient computation.

These two alternative definitions correspond to a different form of density estimation based on determining the radius of the smallest neighborhood of the point containing a fixed-size number of data points.

The advantage of distance-based definitions w.r.t. statistical tests is that there is no need to know the form of the distribution underlying the data and/or the parameters associated with that distribution. Moreover, distance-based outliers are suitable even in situations when the dataset does not fit any standard distribution.

As an interesting property, it can be shown that in some cases this definition generalizes the definition of outlier in statistics, that is for some known distributions there exists values for the parameters such that finding the distance-based outliers corresponds to determine the less probable observations according to the distribution function at hand, as discussed in Knorr *et al.* (2000) and Angiulli and Fasseti (2009).

Since the distance-based definition detects outliers on the basis of their absolute density, it corresponds to a notion of global outlier, as the outliers are the objects lying in the sparser regions of the feature space. The definition admits more than one generating mechanism or cluster, although they should have similar characteristics. Moreover, it works well even in situations where the geometric intuition is not available, e.g. non-metric spaces, and may exhibit high-ranking performances in high-dimensional spaces.

Distance-based outlier scores are monotonic non-increasing with respect to the portion of the dataset already explored. This property allows to design effective pruning rules and very efficient algorithms.

The DOLPHIN algorithm (Angiulli and Fasseti, 2009) is a state-of-the-art technique for detecting distance-based outliers w.r.t. parameters R and k . It is able to work with disk resident datasets and performs only two data scans. It has low main memory requirements and integrates pruning rules and indexing strategies. This method is very fast and able to manage large collections of data. Its temporal cost is linear in the dataset size, being $O(n d k/p)$, where n is the number of dataset points, d is the data dimensionality, and $p < 1$ is a constant which depends on the data distribution. It is very profitable for metric data, but can be used with any type of data for which a distance function is defined.

Density-Based Outliers

Despite the name usually employed to refer this family of techniques, density-based outlier definitions detect outliers on the basis of their *relative density*.

Indeed, differently from distance-based definitions, which declare as outliers the points where the estimated data density is low, density-based definitions score points on the basis of the degree of disagreement between the estimated density of the point and the estimated density of its surrounding or neighboring points.

Thus, this family of definition are better characterized as a notion of local outlier. Indeed, a relatively high density point could be a density-based outlier, provided that it is located close to a region of much higher density. This situation typically occurs when

the point lies on the border of a cluster. This makes these techniques very suitable to isolate outliers in data containing sub-populations or clusters of varying density and, hence, with markedly different characteristics.

A way to define the density of a point is to consider the average distance to its k -nearest neighbors, which is similar to the distance-based definition provided in Angiulli and Pizzuti (2005):

$$dens_k(x) = \left(\frac{\sum dist(x, y)}{|N_k(x)|} \right)^{-1}$$

where $N_k(x)$ denotes the set of points whose distance from x is not greater than the distance separating x from its k -th nearest neighbor.

Density-based outliers score points on the basis of their *relative density*, that is the ratio between the density of a point and the average density of its nearest neighbors:

$$score_k(x) = \frac{dens_k(x)}{(\sum dens_k(y))/|N_k(x)|},$$

Density-based outlier methods have been introduced in Breunig et al. (2000) with the Local Outlier Factor (LOF) measure. LOF measures the degree of an object to be an outlier by comparing the density in its neighborhood with the average density in the neighborhood of its neighbors. Thus, the formalization of the LOF score is very similar to the relative density score above reported, with some minor modifications aiming to mitigate the effect of statistical fluctuations of the distance.

Advantages of the LOF score are that it is able to identify local outliers, and that the definition can be applied in any context a dissimilarity function can be defined. Moreover, experimentally works well in different scenarios, e.g. in network intrusion detection.

However, the geometric intuition of LOF is only applicable to low dimensional vector spaces. Also, the LOF score is difficult to interpret: a value of 1 or even less indicates a clear inlier, but there is no clear rule for when a point is an outlier. Moreover, finding LOF outliers is costly, since in principle the exact k -nearest neighbors of each point are required, which in the worst case costs $O(n^2)$.

The Multi-granularity DEviation Factor (MDEF), introduced in Papadimitriou et al. (2003), represents an alternative definition of relative density. This time the density of an object is defined on the basis of the number of objects lying in its neighborhood, that is a fixed-radius hypersphere centered on the point.

The Gradient Outlier Factor (GOF) (Angiulli and Fassetti, 2016) represents an alternative notion of local outlier. Let $\rho(t)$ a function which is maximum in $t=0$ and tends to 0 for arbitrarily large t values, e.g. $\rho(t)=1/(1+t)$. Given a dataset, it is assumed that it is generated by a random variable X having unknown pdf f . The domain neighborhood $N_f(x)$ of x is the neighborhood of x having radius $\rho(\|\nabla f(x)\|)$, where $\nabla f(x)$ denotes the gradient of the function f evaluated in x . Intuitively the size of $N_f(x)$ is inversely proportional to the slope of f in x . The GOF is defined as the probability

$$GOF(x) = Pr[X \in N_f(x)] = f(x) \cdot \rho(\|\nabla f(x)\|)$$

to observe a data value in the domain neighborhood of x . The form of f is determined by exploiting Kernel Density Estimation (Scott, 1992).

This definition encompasses some desirable characteristics of various existing definitions that are the unification with the statistical definition, as in the case of the distance-based definitions, the ability to deal with different populations or to capture local outliers, as in the case of the density-based definitions, and the ability to detect some subtle form of anomalies, as in the case of abnormal concentrations of objects.

The Outlier Detection using Indegree Number (ODIN) algorithm (Hautamaki et al., 2004) exploits the notion of reverse nearest neighbor to isolate outliers and due to the nature of the detected outliers can be assimilated to local outlier definitions. A point y is a k -reverse nearest neighbor of x , if x is among the k -nearest neighbors of y . The score of a point x is the number of k -reverse nearest neighbors of x . Intuitively, points associated with low scores are unlikely to be selected as neighbors by any other point, and this witnesses for their outlierness.

The Concentration Free Outlier Factor (CFOF), introduced in Angiulli (2017), is a score particularly suitable for high dimensional data. Specifically, the CFOF score of the point x is given by the smallest integer k for which x is a k -nearest neighbor of at least the ρ fraction of the data, where $\rho \in (0, 1)$ is an input parameter. This definition is adaptive to different density levels and has the peculiarity to resist to curse of dimensionality related phenomena, such as the tendency of distances to become almost similar as the dimensionality increases.

Isolation-Based Outliers

The basic idea of *Isolation Forest* (iForest) (Liu et al., 2012) is to detect outliers on the basis of their inclination to be isolated from the rest of the data. Since anomalies are few and different, they are identified as the objects more susceptible to isolation.

With this aim the Isolation Forest technique builds a data-induced tree, also called Isolation Tree (or *iTree*) by recursively and randomly partitioning instances, until all of them are isolated. The random partitioning produces shorter paths for anomalies.

More formally, an *iTree* is a binary tree T associated with a subset of the data points, whose internal nodes consist of two childs, T_l and T_r , and one test, while external nodes (leafs) consist of one single point. The test consists of an attribute a and a split value v

such that the condition $a < v$ partitions data points associated with T into T_l and T_r . The *Path Length* $h(x)$ of a point x in T is the number of edges transversed in order to reach the external node containing x .

An iTree is built by recursively expanding non-leaf nodes (initially all the data is associated with a single internal node) by randomly selecting an attribute a and a split value v .

Due to the random nature of each iTree, to assess result quality a collection of iTrees is randomly built. The anomaly score $s(x)$ of x is then defined in terms of its average path length. Specifically:

$$s(x) = 2^{-\frac{E[h(x)]}{c(n)}}$$

where $E[h(x)]$ denotes the average path length of x in the collection of iTrees and $c(n)$ is a normalization constant which depends on the total number of data points.

To gain efficiency and ameliorate quality, subsampling is employed during collection building. Advantages of this approach are that it has a linear time complexity with a low constant and low memory requirements, due to subsampling.

However, the approach can be used only on ordered domains and does not support categorical attributes. Moreover there is no clear semantics, even if outliers may have different nature than those detected by other approaches, as distance- and density-based methods.

Angle-Based Outliers

In some applications dealing with high-dimensional data, angles are considered more reliable than distances. Think, e.g., to the text mining field, where the cosine distance, measuring the angle between two data points, is employed as a dissimilarity measure.

The Angle-Based Outlier Factor (ABOF) has been designed for high-dimensional data and, following the above perspective, scores data points on the basis of the variability of the angles formed by a point with each other pair of points.

The intuition is that for a point within a cluster, the angles between difference vectors to pairs of other points differ widely, while the variance of these angles will become smaller for points at the border of a cluster and for isolated points.

Formally, the angle-based outlier factor $ABOF(\vec{A})$ is the variance over the angles between the difference vectors of $\vec{A}$ to all pairs of points in the dataset D , weighted by the distance of the points:

$$ABOF(\vec{A}) = \text{VAR}_{\vec{B}, \vec{C} \in D} \left(\frac{\langle \vec{AB}, \vec{AC} \rangle}{\|\vec{AB}\|^2 \|\vec{AC}\|^2} \right)$$

where $\vec{BC}$ denotes the difference vector $\vec{C} - \vec{B}$ and the computation takes into account only triples $(\vec{A}, \vec{B}, \vec{C})$ where the three points are mutually different.

A problem with this definition is that since for each point all pair of other points must be considered, the temporal cost is very high, that is cubic $O(n^3)$.

The *approxABOF* score approximates the ABOF one by considering only the pairs of points with the strongest weight in the variance, that are the k nearest neighbors. This approximation results in an acceleration, with temporal cost $O(n^2 + n k^2)$. However, the quality of the approximation usually deteriorates with increasing dimensionality and the latter definition is only suitable for low-dimensional datasets.

Subspace-Based Outliers

Traditional outlier detection methods search for anomalies by taking into account the full feature space. However, in many situations points exhibit exceptional behavior only when the analysis is focused on some subset of the features, also called a subspace.

These techniques can be grouped in two categories, subspace-based outlier detection, which search for outliers in an unsupervised manner by restricting attention to subset of features, and outlier explanation techniques, which try to explain the abnormality of a user-provided outlier by singling out the subspace that most differentiates it from the rest of the data population.

In both cases, techniques have to deal with the enormous search space, having exponential size in the number of attributes, composed by all the subsets of the overall set of attributes.

Knorr and Ng (1999) focus on the identification of the intensional knowledge associated with distance-based outliers. First, they detect the outliers in the full attribute space and then, for each outlier o , they search for the subspace that better explains why it is exceptional, that is the minimal subspace in which o is still an outlier.

A popular method for finding outliers in subspaces is due to Aggarwal and Yu (2001), which detects anomalies in a d -dimensional dataset by identifying abnormal lower dimensional projections. Each attribute is divided into equi-depth ranges, and then k -dimensional hypercubes ($k < d$) in which the density is significantly lower than expected are searched for. The search technique is based on exploiting evolutionary algorithms.

Subspaces can be useful to perform *example-based* outlier detection: a set of example outliers is given as input and the goal is to detect the dataset objects which exhibit the same exceptional characteristics as the example outliers. Zhu et al. (2005) accomplish

this task by means of a genetic algorithm searching for the subspace minimizing the density associated with hyper-cubes containing user examples.

The approach (Dang *et al.*, 2014) considers the problem of detecting and *interpreting* local outliers, i.e., objects which are outliers relative to a subpopulation of neighbors, rather than the entire dataset. The outlierness is measured in a low-dimensional subspace capable of preserving the locality around the neighbors while at the same time maximizing the distance from the outlier candidate. Incidentally, the low-dimensional transformation also provides the insights for the relevant features which contribute most to the outlierness.

Outlier Ensembles

Ensemble analysis is a method used in data mining to reduce the dependence of the model on the specific dataset. The basic idea is to combine the results from different models in order to obtain a more robust one. This kind of approach has been widely applied to clustering and classification, while less attention has been devoted to its applicability in the context of outlier detection.

The basic ensemble algorithm (i) computes different outlier scores for a point using the output of different outlier detection algorithms and then (ii) combines the scores from different algorithms to obtain a more robust final score.

One of the first approaches to outlier ensembles is due to Lazarevic and Kumar (2005), which proposed to exploit subspaces to improve accuracy. Specifically, they experimented feature bagging: the same outlier detection algorithm is executed multiple times, each time considering a randomly selected set of features from the original feature set, and finally outlier scores are combined in order to find outliers of better quality.

Both Aggarwal (2012) and Zimek *et al.* (2013) report a comparison of existing outlier detection ensemble techniques and of the associated characteristics. Specifically, designing a good ensemble involves the following main challenges: the proper selection of the algorithms to employ, the normalization of the scores to be combined, and the selection of the strategy to combine scores.

The first issue, that is important for building good ensembles, should guarantee the diversity of the models. Aggarwal (2012) proposed a categorization of ensemble approaches to outlier detection by distinguishing between independent ensembles and sequential ensembles, and between model-centered ensembles and data-centered ensembles.

In independent ensembles the executions of the algorithms are independent each other, while in sequential ensembles the executions of the algorithms depend from the results of the past executions so that the models can be successively refined.

Moreover, a model-centered ensemble combines the output of different algorithms executed on the same data, while a data-centered ensemble combines the output of the same algorithm executed on different derivations, in the form of subsets and/or subspaces, of the same data.

As for other issues, since due to the different nature of the various unsupervised outlier detection approaches proposed in the literature the associated score are non-homogeneous, Gao and Tan (2006) proposed techniques for converting output scores from different outlier detection algorithms into probability estimates.

Outlier Explanation

In many real situations one is given a data population characterized by a certain number of attributes, and information are provided that one of the individuals in that data population is abnormal, but no reason whatsoever is given as to why this particular individual is to be considered abnormal. Outlier explanation techniques precisely try to explain the abnormality of an user-provided outlier by singling out the subspace that most differentiate it from the rest of the data population.

The technique introduced in Angiulli *et al.* (2009) provides explanations for a given outlier in a categorical dataset in the form of explanation-outlying property pairs. To illustrate, consider a table reporting some of the attributes collected for some animals. It is known that the platypus is an exceptional animal being it a mammal, but laying eggs. This knowledge can be formalized by noticing that among dataset objects having value “true” for the attribute “eggs”, the platypus is the only animal having value “true” for the attribute “milk”. Obviously the value “true” for the attribute “milk” is not an exceptional feature per se, but it is surprising when attention is restricted to the animals which lay eggs. This is a case where an outlying property is individuated, where the attribute “eggs” plays the role of explanation for the outlying property “milk” of the platypus.

More formally, a *property* (set of attributes) P is *outlying* for an object x , if the frequency of the combination of values assumed by x on the attributes in P is rare if compared to the frequencies associated with the other combinations of values assumed on the same attributes by the other objects of the dataset. Moreover, E is an *explanation* (set of attributes) for p and x , if restricting the attention to the subset of dataset objects sharing with x the same values on the attributes in E , makes p an outlying property for x . Thus, in the example above $E = \text{“eggs”}$ is an explanation for the outlying property $P = \text{“milk”}$ and the object $x = \text{“platypus”}$.

This approach, which consists in determining the typicality of frequency values, is more robust than directly considering absolute frequency values. As an example, consider a key attribute: obviously the value assumed by any object on that attribute occurs just once on the dataset, but this cannot be considered exceptional since all the other values occur once.

The technique was applied in Angiulli *et al.* (2009) to the analysis of a genetic dataset concerning genotype information from the DNA of subjects born in Calabria. Specifically, for each individual the stored information concerned ten polymorphic genetic loci and the analysis consisted in the explanation of longevous individuals.

The approach above depicted is extended to the handling of numerical attributes in Angiulli *et al.* (2017) and to the simultaneous explanation of groups of outliers in Angiulli *et al.* (2013).

In Micenkova *et al.* (2013), the authors assume that outliers are given in input and their objective is to find an *explanatory subspace*, that is a subspace of the original numerical attribute space where the outlier shows the greatest deviation from the other points. The basic idea of the algorithm is to encode the notion of outlierness as separability: given an object x deemed as an outlier, one can devise an artificial set of points X oversampled from a gaussian distribution centered in x . Then, the outlierness of x can be measured in terms of the accuracy in separating the artificial points X from the other points in the dataset. Having encoded the outlierness as a classification problem, the explanatory subspace can hence be reduced to feature selection relative to such a classification problem.

Duan *et al.* (2015) propose a method based on ranking and searching. Given a subspace, the method ranks the query object within the subspace according to a density-based outlierness measure. Then explanations are provided as those minimal subspaces for which the rank is minimum.

There are some substantial differences between these two approaches and the preceding ones. In the latter approaches it is assumed that outlierness is relative to the whole population, and methods return individual subspaces where the query object is mostly outlying comparing to the other subspaces. By contrast, the former approaches model the scenario where the outlierness can be expressed relative to a homogeneous subpopulation. In this respect, the meaning of the two types of explanations is fundamentally different.

Closing Remarks

Outlier detection is a fundamental data analysis tool having several applications in different domains. We surveyed the main families of unsupervised data mining techniques for the detection of anomalies. The discussed approaches are characterized by different modalities of perceiving the abnormality of a given observation. Understanding their peculiarities is of help to the analyst during the process of selection of the right technique to apply to the data at hand. The analysis included statistical-based, distance-based, density-based, isolation-based, angle-based, subspace-based, ensembles, and methods providing explanations. The above methods can be generally applied to data modelled by several features or on which a notion of distance is defined. The field of outlier detection is an active one, with several techniques developed also in the context of specific data types not explicitly considered here, including, e.g., spatial data (Chen *et al.*, 2008), sequential and temporal data (Chandola *et al.*, 2012), and network structured data (Akoglu *et al.*, 2015).

Biographical Sketch

Fabrizio Angiulli received the Laurea degree in computer engineering in 1999 from the University of Calabria (UNICAL). He is an associate professor of computer engineering since 2011 at DIMES Department, University of Calabria, Italy. In 2013, he obtained the Italian Full Professor qualification. Previously, he held a research and development position at ICAR of the National Research Council of Italy and, after that, a tenured assistant professor position at DEIS, University of Calabria. His main research interests are in the area of data mining, notably outlier detection and classification techniques, knowledge representation and reasoning and database management and theory. He has authored more than 80 papers appearing in premier journals and conference proceedings. He regularly serves on the program committee of several conferences and, as an associate editor, on the editorial board of the *AI Communications* journal. He is a senior member of the IEEE.

Introduction

High-throughput experimental processes in various data driven computing domains have led to the availability or production of massive amounts of data. Explosive data growth can definitely be witnessed in biological research, and is due to revolutionary changes in how high throughput experiments are conducted in biomedical sciences and in biotechnology. A wide spectrum of biomedical data is generated by experiments in clinical and therapeutic investigations. Omics research, involving high throughput Next Generation Sequencing (NGS) and Microarray technologies, have been instrumental in generating massive amounts of mRNA, miRNA and gene expression data, as well as Protein-Protein Interaction data. Rapid and massive data generation sources lead to subsequent challenges in effective data storage and transmission. Efficient and scalable exploratory data mining techniques provide an emerging and important set of tools for knowledge discovery from *in silico* data sources (Roy *et al.*, 2013). A plethora of data mining and machine learning methods have been proposed, over the last several decades, to explore and discover hidden and unknown biological facts and relationships among biological entities.

Inference and analysis outcomes produced by knowledge discovery methods are highly dependent on the quality of the input data. A highly effective method is generally incapable of producing reliable results in the absence of high quality data. Biological data are generated and distributed across the globe. Heterogeneity in data due to different data acquisition techniques and standards, with non-uniform devices in geographically distributed research laboratories, makes the task of producing high quality data a near impossibility in many cases.

In general, real world data are of poor quality and can not be directly input to sophisticated data mining techniques. Such data are also often incomplete. As a result, it may be difficult to discover hidden characteristics, which may be of interest to the domain expert, or the data may contain errors, technically referred to as outliers. The interpretation of this type of data may also require understanding of the background knowledge used when analyzing the data. The same set of data can be represented in multiple formats and the values may have been normalized to different ranges, depending upon the statistical validity and significance. To use data mining techniques to mine interesting patterns from such data, they need to be suitably prepared beforehand, using data Pre-processing. Data pre-processing is a sequence of steps comprising Data Cleaning, Data Reduction, Data Transformation and Data Integration. Each step is equally significant, independent and can be executed in isolation. It is the data and the tasks to be performed which determine the step(s) to be executed and when. A domain expert's intervention may be necessary to determine the appropriate steps for a particular dataset. It is not appropriate to use the steps simply as a black-box.

High throughput technologies such as Microarray and Next Generation Sequencing (NGS) typically assess relative expression levels of a large number of cDNA sequences under various experimental conditions. Such data contain either time series measurements, collected over a biological process, or comparative measurements of expression variation in target and control tissue samples (e.g., normal versus cancerous tissues). The relative expression levels are represented as ratios. The original gene expression data derived after scanning the array, i.e., the fluorescence intensities measured on a microarray, are not ready for data analysis, since they contain noise, missing values, and variations arising from experimental procedures. Similar situations may arise even in RNASeq data derived from NGS. The *in silico* analysis of large scale microarray or RNASeq expression data from such experiments commonly involves a series of preprocessing steps (Fig. 1). These steps are indispensable, and must be completed before any gene expression analysis can be performed.

Data cleaning in terms of noise elimination, missing value estimation, and background correction, followed by data normalization is important for high quality data processing. Gene selection filters out genes that do not change significantly in comparison to untreated samples. In reality, not all genes actively take part in a biological activity, and hence are likely to be irrelevant for effective analysis. The intention is to identify the smallest possible set of genes that can still achieve good performance for the analysis under consideration (Daz-Uriarte and De Andres, 2006). Gene expression levels of thousands of genes are stored in a matrix form, where rows represent the relative expression level of the gene w.r.t. to sample or time. Performing a logarithmic transformation on the expression level, or standardizing each row of the gene expression matrix to have a mean of zero and a variance of one, are common pre-processing steps.

We now discuss the major data pre-processing steps in detail.

Data Cleaning

Quality of data plays a significant role in determining the quality of the resulting output when using any algorithm. Data cleaning is one such step in creating quality data (Herbert and Wang, 2007). It usually handles two situations, which give rise to

Fig. 1 Commonly used preprocessing steps for gene expression data analysis.

inconsistent input, missing values, misspellings, etc. The first deals with missing values, and the second is the data duplication problem. The presence of duplicate data adds to the computation time without adding any extra benefit to the result.

Handling Missing Value

A major issue that arises during pre-processing of data is that of missing values. A missing value occurs when the value of data example is not stored for a variable or feature of interest. Missing values can lead to serious issues, whether it is poor representation of the overall dataset in terms of its distribution, or bias in the results obtained (Hyun, 2013). Therefore, they need to be handled cautiously so as to enhance the performance of the methods. Missing data can occur because of a number of technical reasons. These may be one of the following:

- Malfunctioning or physical limitations of the measuring equipment may lead to some values being not recorded. Even interruptions in communication media during transportation of data may lead to missing values.
 - A few missing values may not seem to be important during the data collection phase, and corrective measures may not have been taken, at a later stage, to determine them.
 - Some values may have been removed due to inconsistency with other recorded data.
- There can be various types of missing data (Allison, 2012). These are broadly classified as follows.
- Missing Completely at Random (MCAR): When the probability of a missing observation is not related to the estimated value.
 - Missing at Random (MAR): When the probability of a missing observation is unrelated to its value, but depends on other aspects of the observed data.
 - Missing Not at Random (MNAR): If the missing data values do not belong to either of the above two categories, then it is said to be in MNAR, i.e., the probability of a missing observation is related to its value.

We explain the above types of missing data values with the help of an example. Suppose that we have two variables a and b , whose values are represented by vectors, A and B , respectively. Suppose that the individual values in vector B are always recorded, however, vector A has missing values. A missing value in A is said to be MCAR if the chance of it being missing is independent of values recorded in both A and B . On the other hand, if the probability of a missing value in A is likely to depend on the values in B , but is independent of the values of A , it is termed as MAR.

There are various approaches to handling missing data. It is possible to ignore the missing data completely, but if the amount of missing data is a large proportion of the dataset, this approach may severely affect the quality of the results. Also, if there are cases of MNAR missing values, they require parameter estimation to model the missing data. In order to deal with missing data, four broad classes of alternatives are available.

Ignoring and discarding data

Ignoring the missing values in the data is the simplest way to handle this issue. However, this is appropriate only for the MCAR situation. If we apply this treatment to other situations, we are likely to introduce bias in the data, and ultimately in the end results. Discarding missing data can be done in two ways: *complete case analysis* and *attribute discarding*. Complete case analysis is the *de facto* method, and is available in many programs. It discards all instances with missing data, and further analysis is carried out only on the remaining data.

The second way to discard attributes involves determining the extent to which the data is missing with respect to the number of instances, and the relevance of the attributes in the whole dataset. Based on that, one can discard or remove instances that are not widespread or whose relevance w.r.t. the whole dataset is not very significant. Note that if an attribute with missing values has very high relevance, it has to be retained in the dataset, as in Batista and Monard (2002).

Parameter estimation

This approach is suitable for MNAR missing data. It requires estimation of parameters using suitable models such as probabilistic, KNN, or SVD models. In order to estimate the parameters of a model, the maximum likelihood approach, using a variant of the

Expectation-Maximization algorithm can be used (Moon, 1996). The most common method using this approach is called BPCA (Oba *et al.*, 2003) which consists of three elementary steps – principal components regression, Bayesian estimation, and an iterative Expectation-Maximization (EM) algorithm. This is most commonly used in biological data cleaning.

Imputation

In the context of missing data, imputation refers to the consequence of actions taken to address the case of missing data. The aim of imputation is to replace the missing data with estimated values by using information in the measured values to infer population parameters. It is unlikely to give the best prediction for the missing values, but can certainly add to the completeness of the dataset (Little and Rubin, 2014). Imputation approaches can be broadly divided into *Single value imputation*, the *Hot deck and cold deck method*, and *Multiple imputation*.

1. Single value imputation: Single value imputation replaces the missing value with a single estimated value, which is assumed to be very close to the value that would have been observed if the dataset were complete. Various means for substituting a single value for the missing data are used. Some of these are as follows:
 - (i) Mean imputation: The mean of the existing values of an attribute is used to replace missing attribute value. This approach, reduces the diversity of data and therefore tends to produce a poorer estimation of the standard deviation of the dataset (Baraldi and Enders, 2010).
 - (ii) Regression imputation: A regression model can be used to predict observed values of a variable based on other variables, and that value is used to impute values in cases where that variable is missing. It preserves the variability in the dataset without introducing bias in the results. It overestimates the correlation between the attributes as compared to mean imputation, which underestimates this measure due to the loss of variability.
 - (iii) Least squares regression (LS impute): It is an extended form of the regression model. It is calculated by developing an equation for a function that minimizes the sum of squared errors from the model (Bø *et al.*, 2004).
 - (iv) Local least squares (LLS impute): It is similar to LS impute, except that it involves a *priori* step before applying the regression and estimation. It first represent a target gene that has missing values using a linear combination of similar genes by identifying the *K* nearest neighbors that have large absolute values of Pearson correlation coefficients (Kim *et al.*, 2004).
 - (v) K-Nearest Neighbor imputation (KNN impute): Missing data are replaced with the help of known data by minimizing the distance between the observed and estimated values of the missing data. The K-neighbors closest to the missing data are found, and the final result is estimated and replaces the missing value. This substitution of value depends on the type of missing data (Batista and Monard, 2002).
2. Hot deck and cold deck methods: Hot deck imputation involves filling in missing data on variables of interest from non-respondents (or recipients) using observed values from respondents (i.e., donors) within the same survey data set. Depending on the donor with which the similarity is computed, the hot deck approach, which is also known as Last Observation Carried Forward (LOCF), can be subdivided into *random hot deck prediction* and *deterministic hot deck prediction* (Andridge and Little, 2010). The hot deck approach offers certain advantages because it is free from parameter estimation and ambiguities in prediction of values. The most essential feature of this technique is that it uses only logical and credible values for estimating missing data, as these are obtained from the donor pool set (Andridge and Little, 2010). Cold-deck imputation, on the other hand, selects donors from another dataset to replace a missing value of a variable or data item with a constant value from an external donor.
3. Multiple imputation: Multiple imputation involves a series of calculations to decide upon the most appropriate value for the missing data. This technique replaces each missing value with a set of the most suitable values, which are then further analyzed to determine the final predicted value. It follows a monotonic missing pattern which means, for a sequence of values for a variable, if one value is missing then all subsequent values are also missing. Two common methods are used to find the set of suitable values.
 - Regression method: A regression model is fitted for attributes having missing values along with those from previous attributes in the sequence of dataset as covariates, following the monotone property. Based on this model, a new model is formed and this process is repeated sequentially for each attribute with missing values (Rubin, 2004).
 - Propensity score method: The propensity score is the conditional probability of assignment to a particular treatment given a set of observed covariates. In this method, a propensity score is calculated for each attribute with missing values to indicate the probability of that observation being missing. A Bayesian bootstrap imputation is then used on the grouped data based on the propensity score to get the set of values (Lavori *et al.*, 1995).

Duplicate Data Detection

Data redundancy due to the occurrence of duplicate data values for data instances or attributes leads to the issue of shortage of storage. The most common way of handling duplicacy is by finding chunks of similar values and removing the duplicates from the chunks. However, this method is very time consuming and hence a few other techniques have been developed for handling redundant data.

Knowledge-based methods

Incorporating domain dependent information from knowledge bases into the data cleaning task is one alternative for duplication elimination. A working tool based on this technique is Intelliclean (Low *et al.*, 2001). This tool standardizes abbreviations. Therefore, if one record abbreviates the word street as *St.*, and another abbreviates it as *Str*, while another record uses the full word, all three records are standardized to the same abbreviation. Once the data has been standardized, it is cleaned using a set of domain-specific rules that work with a knowledge base. These rules detect duplicates, merge appropriate records, and create various alerts for any other anomalies.

ETL method

The most popular method for duplicate elimination, these days, is the ETL method (Rahm and Do, 2000). The ETL method comprises three steps – extraction, translation, and loading. Two types of duplicate data elimination can be performed using this method – one at the instance-level and the other at the schema-level. Instance-level processing cleans errors within the data itself, such as misspellings. Schema-level cleaning usually works by transforming the database into a new schema or a data warehouse.

Data Reduction

Mining large scale data is time consuming and expensive in terms of memory. It may make the task of data mining impractical and infeasible. Using the entire dataset is not always important, and in fact, may contribute little to the quality of the outcome, compared to using a reduced version of it. Sometimes, the abundance of irrelevant data may lead to non-optimum results. Data reduction reduces the data either in terms of volume or the number of attributes (also called dimensions) or both, without compromising the integrity of the original data with regard to the results. A number of approaches are available for data reduction. Ideally, any data reduction method should be efficient and yet produce nearly identical analytical results to those obtained with the full data. Various approaches are briefly discussed below.

Parametric Data Reduction

In parametric data reduction, the volume of the original data is reduced by considering a relatively compact alternative way to represent the data. It fits a parametric model based on the data distribution to the data, and estimates the optimal values of the parameters required to represent that model. In this approach, only model parameters and the outliers are stored. Regression and non-linear models are two well-known approaches for parametric data reduction.

Unlike parametric, non-parametric approaches do not use any models. They summarize the data with sample statistics, as discussed below.

Sampling

Processing a large data set at one time is expensive, and time consuming. Instead of considering the whole data set, a small representative sample of k instances taken from a data set with G instances, where $|k| \leq |G|$. This process is called sampling. We can categorize sampling as follows.

- Simple random sampling without replacement: Here, a sample of size k is selected from a large data set of size $|G|$ with probability(p), and the samples, once chosen, are not placed back in the dataset. Sampling without replacement gives a non-zero covariance between two chosen samples, which complicates the computations. If the number of data instances are very large, the covariance is very close to zero.
- Simple random sampling with replacement: Here, the sample, once chosen, are placed back in the dataset and hence data may be duplicated in the sample. It gives a zero covariance between two chosen samples. In case of a skewed data distribution, simple random sampling with replacement usually produces poor results with any data analysis method. In such a case, sampling with replacement isn't much different from sampling without replacement. However, the precision of estimates is usually higher for sampling without replacement compared to sampling with replacement. Adaptive sampling methods such as stratified sampling and cluster sampling are likely to improve performance in the case of unbalanced datasets with relatively uneven sample distribution.
- Stratified sampling: In stratified sampling the original data is divided into strata (sub-groups), and from each stratum a sample is generated by simple random sampling.
- Cluster sampling: In cluster sampling, the original data is divided into clusters (sub-groups), and out of a total of N clusters, n are randomly selected, and from these clusters, elements are selected for the creation of the sample.

Dimension Reduction

Dimension or attribute reduction is simply the removal of unnecessary or insignificant attributes. The presence of irrelevant attributes in the dataset may make the problem intractable and mislead the analysis as well, which is often termed the *Curse of*

Dimensionality. Data sets with high dimensionality are likely to be sparse as well. Machine learning techniques such as clustering, which are based on data density and distance, may produce incorrect outcomes, in the case of sparse data. To overcome the low performance of machine learning algorithms with high dimensional data sets, dimension reduction is vital. Dimension reduction should be carried out in such a way that, as much as possible, the information content of the original data remains unchanged and that the use of the reduced dataset does not change the final outcome. Dimension reduction can be obtained by selecting only the relevant attributes and ignoring the rest. Principal Component Analysis (PCA) (Hotelling, 1933) is one of the most commonly used technique for dimensionality reduction. PCA is a statistical procedure that uses an orthogonal transformation to map a set of observations of possibly correlated variables into a set of values of linearly uncorrelated variables called principal components. It finds low dimensional approximations of the original data by projecting the data onto linear subspaces. It searches for k n -dimensional orthogonal vectors ($k < n$) from the original n dimensional data which best represent the original data. The original data are thus mapped onto a much smaller number of dimensions, resulting in dimensionality reduction.

Data Transformation and Normalization

Transformation is the process of converting data from one format or structure into another format or structure. It is applied so that the data may more closely meet the assumptions of a statistical inference procedure, or to improve interpretability. It uses a transformation function, $y=f(x)$, to change data from one domain to another. Often the term *normalization* is interchangeably used with transformation. Normalization means applying a transformation so that the transformed data are roughly normally distributed. Some transformation or normalization techniques are discussed below.

Log₂ Transformation

It is the most widely used transformation in the case of microarray (Quackenbush, 2002) or RNASeq data (Anders and Huber, 2010). It produces a continuous series of values for which it is easy to deal with extreme values, heteroskedasticity, and skewed data distributions.

Min-Max Normalization

It maps an attribute value, x , in the original dataset to a new value, x' , given by

$$x' = \frac{x - \min}{\max - \min}$$

Z-Score Normalization

It transforms the values of variables based on their mean and standard deviation. For a variable X represented by a vector $\{x_1, x_2, \dots, x_n\}$ each attribute can be transformed using the formula

$$x'_i = \frac{x_i - \bar{X}}{std_{dev}(\bar{X})}$$

where x'_i is the Z-score value of x , $\bar{X}$ is the row mean of X , std_{dev} is the standard deviation given by

$$std_{dev}(\bar{X}) = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{X})^2}$$

Decimal Scaling Normalization

Decimal scaling moves the decimal point of a attribute value. The number of decimal points moved depends on the maximum absolute value of the attribute. A value v of an attribute is normalized to v' by following way:

$$v' = \frac{v}{10^j}$$

where j is the smallest integer such that $\max(v') < 1$. Suppose that the values of an attribute ranges from 523 to 237. The maximum absolute value is 523. To normalize by decimal scaling, it divides each value by 1000 (i.e., $j=3$) so that 523 normalizes to 0.523 and 237 normalizes to 0.237.

Quantile Normalization

It is a technique for making two or more distributions identical in terms of statistical properties. It is frequently used in microarray data analysis (Bolstad et al., 2003). To normalize gene expression data, it first assigns a rank to each column of values based on

lowest to highest values in that column. It then rearranges the column values based on their original values (before ranking), so that each column is in order, going from the lowest to the highest value. The average for each row is then calculated using the reordered values. The average value calculated in the first row will be lowest value (rank 1) from every column, the second average value will be the second lowest (rank 2) and so on. Finally, it replaces the original values with the average values based on the ranks assigned during first step. The new values in each column all have the same distribution.

The quantile normalization transforms the statistical distributions across samples to be the same and assumes there are no global differences in the distributions of the data in each column. However, it is not clear how to proceed with normalization if these assumptions are violated. Recently, a generalization of quantile normalization, referred to as smooth quantile normalization (qsmooth) (Hicks *et al.*, 2016), has been proposed that relaxes the assumptions by allowing differences in the distribution between the groups.

Data Discretization

Data collected from different sources are found in different formats depending on the experimental set-up, prevailing conditions, and variables of interest. To analyze such data, it is often convenient and effective to discretize the data (Dash *et al.*, 2011). Discretization transforms the domain of values for each quantitative attribute into discrete intervals. Using discrete values during data processing offers a number of benefits such as the following:

- Discrete data consumes less memory for storage.
- Discrete data are likely to be simpler to visualize and understand.
- Performance, in some systems, often becomes more efficient and accurate using discrete data.

The two terms frequently used in the context of discretization or interval generation are discussed below.

- Cut-points: Cut-points are certain values within the range of each discretized quantitative attribute. Each cut-point divides a range of continuous values into successive intervals (Liu *et al.*, 2002). For example, a continuous range $\langle a \dots b \rangle$ may be partitioned into intervals like $[a, c]$ and $[c, b]$, where the value c is a cut-point.
- Arity: Another term that is popular in discretization context is Arity. It is the total number of intervals generated for an attribute after discretization. Arity for an attribute is one more than the number of cut-points used for discretization (Liu *et al.*, 2002). An overly high Arity can make the learning process longer while a very low Arity may negatively affect the predictive accuracy.

Any discretization method follows the enumerated steps below.

1. Sort the domain of continuous values for each attribute to be discretized.
2. Evaluate the cut-points for each of these attributes.
3. Create intervals using the deduced cut-points.
4. Assign each value with the alternative value according to the interval in which it falls.

In order to accomplish this set of steps, a discretizer has to use a certain measure to evaluate cut-points and group different continuous values into separate discretized intervals. A few such measures are discussed below.

- Binning: The simplest method to discretize a continuous-valued attribute is by creating a pre-specified number of bins. These cut-points of the bins are determined by user input.
- Entropy: It is one of the most commonly used discretization measures in the literature. It is the average amount of information per event, where the information of an event is high for unlikely events and low otherwise. In every iteration, it calculates the entropy of the bin after splitting and calculates the net entropy of the split and the information gain (Ross Quinlan, 1986). It selects the split with the highest gain and iteratively partitions each split until the gain falls below a certain threshold.
- Dependency: It is a measure that finds the strength of association between a class and a attribute (depending upon certain computations or statistics) and accordingly determines the cut-points. In this measure, the Arity of each attribute has to be specified as a parameter.

Several discretization techniques have been proposed in the literature. They are broadly classified as Supervised and Unsupervised discretization techniques, depending on whether they use any class levels (Mahanta *et al.*, 2012). These are discussed below.

Supervised data discretization

Such discretization uses class labels to convert continuous data to discrete ranges derived from the original dataset (Dougherty *et al.*, 1995). These are of two types.

- (i) Entropy Based Discretization Method: This method of discretization uses the entropy measure to decide the boundaries. Chiu *et al.* (1990) proposed a hierarchical method that maximizes the Shannon entropy over the discretized space. The method starts with k -partitions and uses hill-climbing to optimize the partitions, using same entropy measure to obtain finer intervals.

- (ii) Chi-Square Based Discretization: It uses the statistical significance test (Chi-Square test) (Kerber, 1992) to determine the probability of the similarity of data in two intervals. It starts with every unique value of the attribute in its own interval. It computes χ^2 for each initial interval. Next, it merges the intervals with the smallest χ^2 values. It repeats the process of merging until no more satisfactory merging is possible based on the χ^2 values.

Unsupervised data discretization

The unsupervised data discretization process does not use any class information to decide upon the boundaries. A few discretization techniques are discussed below.

- (i) Average and Mid-Ranged value discretization: A binary discretization technique that divides the class boundaries using the average value of the data. Values less than the average correspond to one class, and values greater than the average correspond to the other class (Dougherty et al., 1995).

For example, given $A = \{23.73, 5.45, 3.03, 10.17, 5.05\}$ the average discretization method first calculates the average score, $\bar{A} = \sum_{i=1}^n A_i$. Based on this value, it discretizes the vector using following equation.

$$D_i = \begin{cases} 1, & \text{if } A(i) > \bar{A} \\ 0, & \text{otherwise} \end{cases}$$

In our example, $\bar{A} = 9.486$, and therefore, the discretized vector using average-value discretization is $D = [1 \ 0 \ 0 \ 1 \ 0]$.

On the other hand, mid-range discretization uses the middle or mid-range value of an attribute in the whole dataset to decide the class boundary. The mid-range of a vector of values is obtained using the equation

$$M = (H + U) / 2$$

where, H is the maximum value and U is the minimum value in the vector. Discretization of values occurs as follows.

$$D_i = \begin{cases} 1, & \text{if } A(i) > M \\ 0, & \text{otherwise} \end{cases}$$

For the vector A , we obtain M as 13.38. Therefore, the corresponding discretized vector of values are $D = [1 \ 0 \ 0 \ 0 \ 0]$. It is not of much use as it lacks efficiency and robustness (outliers change it significantly) (Dougherty et al., 1995).

- (ii) Equal Width Discretization: Divides the data into k equal intervals. The upper and lower bounds of the intervals are decided by the difference between the maximum and minimum values for the attribute of the dataset (Catlett, 1991).

The number of intervals, k , is specified by the user, and the lower and upper boundaries, p_r and p_{r+1} of the class are obtained from the data (H and U , respectively) in the vector according to the equation

$$p_{r+1} = p_r + (H - U) / k$$

For our example, if $k=3$, the class division occurs as given below.

$$D_i = \begin{cases} 1, & \text{if } p_{r_0} < A(i) < p_{r_1} \\ 2, & \text{if } p_{r_1} < A(i) < p_{r_2} \\ 3, & \text{if } p_{r_2} < A(i) < p_{r_3} \end{cases}$$

Therefore, the corresponding discretized vector is $D = [3 \ 1 \ 1 \ 2 \ 1]$.

Some of the frequently used discretizers, out of the plethora of techniques available in literature, are reported in Table 1.

Table 1 Some discretizers and their properties

Discretizer	Measure used	Procedure adopted	Learning model
Equal width	Binning	Splitting	Un-supervised
Equal frequency	Binning	Splitting	Un-supervised
ChiMerge (Kerber, 1992)	Dependency	Merging	Supervised
Chi2 (Liu and Setiono, 1997)	Dependency	Merging	Supervised
Ent-minimum description length principle (MDLP) (Fayyad and Irani, 1993)	Entropy	Splitting	Supervised
Zeta (Ho and Scott, 1997)	Dependency	Splitting	Supervised
Fixed frequency	Binning	Splitting	Un-supervised
Discretization (FFD) (Yang and Webb, 2009)			
Optimal flexible frequency discretization (OFFD) (Wang et al., 2009)	Wrapping	Hybrid	Supervised
Class-attribute interdependence	Dependency	Splitting	Supervised
Maximization (CAIM) (Kurgan and Cios, 2004)			
Class attribute dependent discretization (CADD) (Ching et al., 1995)	Dependency	Hybrid	Supervised
Ameva (Gonzalez-Abril et al., 2009)	Dependency	Splitting	Supervised

Data Integration

Biological data deal with properties of living organisms, i.e., data are associated with metabolic mechanisms. Such data result from the combined effect of complex mechanisms occurring in the cell, from DNA to RNA to Protein, and further to the metabolite level. Understanding cellular mechanisms from all these perspectives is likely to produce more biologically relevant results than simply analyzing them from mathematical or computational viewpoints. Such an analysis involves data integration. Data integration is the process of analyzing data obtained from various sources, and obtaining a common model that explains the data (Schneider and Jimenez, 2012). Such a model fits the prevailing conditions better and makes more accurate predictions. Literature has shown that the use of data integration in the biological sciences has been effective in tasks such as identifying metabolic and signaling changes in cancer by integrating gene expression and pathway data (Emmert-Streib and Glazko, 2011), thereby identifying protein related disorders through combined analysis of genetic as well as genomic interactions (Bellay *et al.*, 2011).

From the systems biological perspective, integration of data can be achieved at three levels, viz., at the data level, at the processing level, or at the decision level (Milanesi *et al.*, 2009). Integrating data at the first level requires combining data from heterogeneous sources and implementing a universal query system for all types of data involved. This is the most time-consuming step in data integration. One needs to consider various assumptions and experimental setup information before combining the data. The second level of data integration involves an understanding and interpretation of the datasets. In this stage of integration, one needs to identify associated correlations between the various datasets involved. The third stage of data integration is at the decision level. In this stage, different participating datasets are first dealt with using specific procedures and individual results are obtained. Finally, these individual results are mapped, according to some ontology or information known *a priori* to interpret the results with more confidence.

Conclusions

Real-life data tend to be incomplete in nature. To handle incompleteness of different forms such as noise, missing values, inconsistencies, and the curse of dimensionality, data preparation steps are essential. We presented a brief discussion of different data preprocessing steps required to make data suitable for analysis. It is well-known that real data are not static in nature and data distributions vary with time. State-of-the-art preprocessing steps are not appropriate to handle such changes of data distribution or characteristics. Dealing with dynamic data is particularly challenging when data are produced rapidly. An empirical study on the suitability and efficiency of pre-processing techniques applied to dynamic data is of great interest for the big data community.

Data Cleaning

Introduction

Raw experimental data is highly susceptible to noise (i.e., contain errors or outliers), missing values (i.e., data lack attribute values, lack certain attributes of interest, or contain only aggregate data) and inconsistency (i.e., data contain discrepancies in codes or names). The representation and quality of the data is crucial because the quality of data affects the data analysis pipeline and thus results. Irrelevant and redundant information in the data, or noisy and unreliable data, could prevent the correct analysis (Han *et al.*, 2012).

Data pre-processing is a fundamental step in the data analysis process to limit such problems. Data pre-processing methods are divided into following categories: (i) data cleaning, that aims to fill in missing values, smooth noisy data, identify or remove outliers, and resolve inconsistencies; (ii) data integration, i.e., the merging of data from multiple data stores; (iii) data transformation, that includes normalization and aggregation methodologies, and (iv) data reduction, that attempts to reduce the volume, but produces the same or similar analytical results. In the following paragraphs, the main data cleaning methodologies are presented and discussed.

Data Cleaning

Data cleaning includes all methodologies whose aims are “detecting and removing errors and inconsistencies from data in order to improve the quality of data” (Lenzerini, 2002). Specifically, data quality methods “clean” the data by filling in missing values, smoothing noisy data, identifying or removing outliers and resolving inconsistencies (Van den Broeck *et al.*, 2005). Instance-level cleaning refers to errors within the data itself; schema level usually concerns integrating the databases into a new schema. Data cleaning is the major part of ETL (extraction, translation and loading) process in data warehouse.

Data Cleaning Methods for Missing Values in Bioinformatics

The presence of missing data may depend on (Herbert and Wang, 2007):

- Malfunctions of data collection systems;
- Inconsistency with values of other data set attributes;
- Not entered data, due to “misunderstanding”;
- Some data may not be considered important at the time of insertion;
- Failure to register changes in data.

There are several approaches to solve missing the data problems. A first approach is “do not do anything”. Some analysis algorithms are quite robust and insensitive to missing data. Another approach is to eliminate the records that contain missing data: this could introduce a distortion in the data. Otherwise, if only few columns have these characteristics it is better to ignore, but this is not very effective. An alternative approach is to predict new values by using different methods. It is possible to use mean or median value or to pad unknown values with zeros. These methods could cause some big imputation errors. To reduce these errors, more sophisticated methods, such as classification/regression techniques, could be used to estimate missing values.

In Liew *et al.* (2011), a comprehensive survey about missing value estimation techniques for microarray gene expression data is reported. A first approach for missing value estimation exploits the correlation structure between entries in the data matrix. In fact, in gene expression data matrix, rows are correlated because the genes involved in similar cellular processes usually have similar expression profiles. Moreover, there is correlation between columns because the set of genes is expected to behave similarly under similar conditions. Thus, missing values estimation can be based on subset of related genes or subset of related conditions. Another approach exploits the domain knowledge about the data or the process that generated the data. A recent work (Wei *et al.*, 2018) present a review and comparison of eight missing values imputation techniques (zero, half minimum, mean, median, random forest, singular value decomposition, KNN and QRILC quantile regression imputation of left-censored data) for different types of missing values using metabolomics datasets. Generally, missing values imputation methodologies could be grouped in the following classes:

- Global approach-based algorithms;
- Local approach-based algorithms;
- Hybrid approach-based algorithms;
- Knowledge assisted approach-based algorithms.

Global Approach-Based Algorithms

Global approach-based algorithms perform missing value estimation analysing the global correlation information of the entire data matrix. The most used algorithms are the Single Value Decomposition (*SVDimpute*) method and the Bayesian Principal Component Analysis (*BPCA*) method (Oba *et al.*, 2003).

SVD method employs singular value decomposition to obtain a set of mutually orthogonal expression patterns that can be linearly combined to approximate the expression of all genes in the data set (Troyauskaya *et al.*, 2001). These patterns, which in this case are identical to the principle components of the gene expression matrix, are referred to as eigengenes. *SVDimpute* first regresses the gene against the k most significant eigengenes and then use the coefficients of the regression to reconstruct the missing values from a linear combination of the k eigengenes.

In *BPCA*, the N -dimensional gene expression vectors γ is expressed as a linear combination of k principal axis vectors v_l . The factor scores w_l and the residual error ϵ are regarded as normally distributed random variables in the probabilistic PCA model (Eq. (1)).

$$\gamma = \sum_k w_l v_l + \epsilon \quad (1)$$

An EM-like algorithm is then used to estimate the posterior distributions of the model parameter and the missing values simultaneously (Liew *et al.*, 2011).

Local Approach-Based Algorithms

The second class of algorithms examine only local similarity structure in the dataset in order to estimate missing value. The most used algorithm is KNN (k -Nearest Neighbors). The KNN-based method (*KNNimpute*) selects genes with expression profiles similar to the gene of interest to impute missing values. If we consider gene A that has one missing value in experiment 1, this method would find K other genes, which have a value present in experiment 1, with expression most similar to A in experiments 2– N (where N is the total number of experiments). A weighted average of values in experiment 1 from the K closest genes is then used as an estimate for the missing value in gene A (Troyauskaya *et al.*, 2001). In the weighted average, the contribution of each gene is weighted by similarity of its expression to that of gene A. Euclidean distance is the most accurate metrics for gene similarity. In Troyauskaya (2001), KNN- and SVD-based methods were compared for DNA microarray missing value estimation. Both methods provide fast and accurate ways of estimating missing values for microarray data and far surpass the traditional accepted solutions, such as filling missing values with zeros or row average, by taking advantage of the correlation structure of the data to estimate missing expression values. Nevertheless, the authors recommend KNN-based method for imputation of missing values, because it shows less deterioration in performance with increasing percent of missing entries. In addition, the *KNNimpute* method is more robust than SVD to the type of data for which estimation is performed, performing better on non-time series or noisy data. *KNNimpute* is also less sensitive to the exact parameters used (number of nearest neighbors), whereas the SVD-based method shows sharp deterioration in performance when a non-optimal fraction of missing values is used.

A number of local imputation algorithms that use the concept of least square regression to estimate the missing values, have been proposed. In least square imputation (*LSimpute*) (Bo *et al.*, 2004), the target gene γ and the reference gene x are assumed to be related by a linear regression model. *LSimpute* first select the K most correlated genes based on absolute Pearson correlation values. Then a least square estimate of the missing value is obtained from each of the K selected genes using single regression. Finally, the K estimates are linearly combined to form the final estimate.

Unlike *LSimpute*, local least square imputation (*LLSimpute*) (Kim *et al.*, 2005) uses a multiple regression model to impute the missing values from all K reference genes simultaneously. Despite its simplicity, *LLSimpute* has been shown to be highly competitive compared to *KNNimpute* and *BPCA* (Brock *et al.*, 2008).

Sequential *LLSimpute* (*SLLSimpute*) is an extension of *LLSimpute* (Zhang *et al.*, 2008). The imputation is performed sequentially starting from the gene with the least missing rate, and the imputed genes are then used for later imputation of other genes. However, only genes with missing rate below a certain threshold are reused since genes with many imputed missing values are less reliable. *SLLSimpute* has been shown to exhibit better performance than *LLSimpute* due to the reuse of genes with missing values.

In iterated *LLSimpute* (*ILLSimpute*) (Cai *et al.*, 2006), different target genes are allowed to have different number of reference genes. The number of reference genes is chosen based on a distance threshold which is proportional to the average distance of all other genes to the target gene. *ILLSimpute* iteratively refines the imputation by using the imputed results from previous iteration to re-select the set of coherent genes to re-estimate the missing values until a preset number of iterations is reached. *ILLSimpute* has been shown to outperform the basic *LLSimpute*, *KNNimpute* and *BPCA* due to these modifications.

In Gaussian mixture clustering imputation (*GMCimpute*) (Ouyang *et al.*, 2004), the data is clustered into S components Gaussian mixtures using the EM algorithm. Then the S estimates of the missing value, one from each component, are averaged to obtain the final estimate of the missing value. The clustering and estimation steps are iterated until the cluster memberships of two consecutive iterations are identical. *GMCimpute* uses the local correlation information in the data through the mixture components.

In Dorri *et al.* (2012) an algorithm that is based on conjugate gradient (CG) method is proposed to estimate missing values. k -nearest neighbors of the missed entry are selected based on absolute values of their Pearson correlation coefficient. Then a subset of genes among the k -nearest neighbors is labeled as the best similar ones. CG algorithm with this subset as its input is then used to estimate the missing values.

MINMA (Missing data Imputation incorporating Network and adduct ion information in Metabolomics Analysis) (Jin *et al.*, 2017) implements a missing value imputation algorithm for liquid chromatography-mass spectrometry (LC MS) metabolomics. MINMA is an R package whose algorithm combines the afore-mentioned information and traditional approaches by applying the support vector regression (SVR) algorithm to a predictor network newly constructed among the features. The software provides a function to match feature m/z values to about 30 positive adduct ions, or over 10 negative adduct ions.

Hybrid Approach-Based Algorithms

The correlation structure in the data affects the performance of imputation algorithms. If the data set is heterogeneous, local correlation between genes are dominant and localized imputation algorithms such as KNNimpute or LLSimpute perform better than global imputation methods such as BPCA or SVDimpute. On the other hand, if the data set is more homogenous, a global approach such as BPCA or SVDimpute would better capture the global correlation information in the data (Liew *et al.*, 2011). Jornsten *et al.* (2005) proposes a hybrid approach called *LinCmb* that captures both global and local correlation information in the data.

In *LinCmb*, the missing values are estimated by a convex combination of the estimates of five different imputation methods: row average, KNNimpute and GMCimpute, that use local correlation information in the estimation of missing values, and SVDimpute and BPCA that are global-based methods for missing values imputation.

To obtain the optimal set of weights that combine the five estimates, *LinCmb* generates fake missing entries at positions where the true values are known and uses the constituent methods to estimate the fake missing entries. The weights are then calculated by performing a least square regression on the estimated fake missing entries. The final weights for *LinCmb* are found by averaging the weights obtained in 30 iterations (Liew *et al.*, 2011).

Knowledge Assisted Approach-Based Algorithms

The algorithms that belong to this category exploit the integration of domain knowledge or external information into the missing values estimation process. The use of domain knowledge has the potential to significantly improve the estimation accuracy, especially for data sets with small number of samples, noisy, or with high missing rate (Liew *et al.*, 2011). Knowledge assisted approach-based algorithms can make use of, for example, knowledge about the biological process in the microarray experiment (Gan *et al.*, 2006), knowledge about the underlying biomolecular process as annotated in Gene Ontology (GO) (Tuikkala *et al.*, 2006), knowledge about the regulatory mechanism (Xiang *et al.*, 2008), information about spot quality in the microarray experiment (Johansson and Hakkinen, 2006), and information from multiple external data sets (Sehgal *et al.*, 2008).

Data Cleaning Methods for Noisy Data in Bioinformatics

Noise is a random error or variance in a measured variable. In biological experiments, such as genomics, proteomics or metabolomics, noise could arise from human errors and/or variability of the system itself. An accurate experimental design and technological advances help to reduce noise, but some uncertainty remains always. Specifically, noisy data could include:

- Input errors due to operators;
- Incorrect data related to transcription operations;
- Input errors due to programs;
- Incorrect data related to programming errors;
- Errors due at a glance of insertion;
- Data stored in different formats for the same attribute.

In the following some methods to manage and pre-process noisy data are described. Binning methods smooth a sorted data value by examining the value of its “neighbourhood”. In smoothing by *bin means*, each value in a bin is replaced by the mean value of the bin. Similarly, smoothing by *bin medians* can be employed, in which each bin value is replaced by the bin median. In smoothing by *bin boundaries*, the minimum and maximum values in a given bin are identified as the bin boundaries. Each bin value is then replaced by the closest boundary value. In general, the larger the width, the greater the effect of the smoothing (Han *et al.*, 2012).

Data smoothing can also be performed by regression. Linear regression involves finding the “best” line to fit two attributes (or variables) so that one attribute can be used to predict the other. Multiple linear regression is an extension of linear regression, where more than two attributes are involved and the data are fitted to a multidimensional surface.

Clustering techniques are also applied to noise detection tasks. Clustering algorithms, used for biological data reduction are particularly sensitive to the noise. In Sloutsky *et al.* (2012), a detailed study relative to the sensitivity of clustering algorithms to noise has been presented, by analysing two different case studies (gene expression and protein phosphorylation).

Another approach employs Machine Learning (ML) classification algorithms, which are used to detect and remove noisy examples.

The work presented in Libralon *et al.* (2009) proposes the use of distance-based techniques for noise detection. These techniques are named distance-based because they use the distance between an example and its nearest neighbors. The most popular distance-based technique is the k-nearest neighbor (k-NN) algorithm. Distance-based techniques use similarity measures to calculate the distance between instances from a data set and use this information to identify possible noisy data. Distance-based techniques are simple to implement and do not make assumptions about the data distribution. However, they require a large amount of memory space and computational time, resulting in a complexity directly proportional to data dimensionality and number of examples., which is the simplest algorithm belonging to the class.

Libralon *et al.* stated that for high dimensional data sets, the commonly used Euclidian metric is not adequate, since data is commonly sparse. Thus, they use the HVDM (Heterogeneous Value Difference Metric) metric to deal with high dimensional data. This metric is based on the distribution of the attributes in a data set, regarding their output values, and not only on punctual values, as is observed in the Euclidian distance and other similar distance metrics.

Outlier Detection

Outliers detection is a fundamental step in the preprocessing stage aiming to prevent wrong results. To detect anomalous measurements and/or observations from normal ones, data mining techniques are widely used (Oh and Gao, 2009). Generally, statistical methods often view objects that are located relatively far from the center of the data distribution as outlier. Several distance measures were implemented, such as Mahalanobis distance. Distance-based algorithms are advantageous since model learning is not required.

Outliers may be detected by clustering, for example, where similar values are organized into groups, or clusters. Values that fall outside of the set of clusters may be considered outliers. In Wang (2008), the authors proposed an effective cluster validity measure with outlier detection and cluster merging strategies for support vector clustering. In Oh and Gao (2009), the authors present an outlier detection method based on KL divergence. Angiulli *et al.* (2006) proposed a distance-based outlier detection method which finds the top outliers and provides a subset of the dataset called outlier detection solving set, that can be used to predict if new unseen objects are outliers.

Concluding Remarks

Data cleaning is a crucial step in data analysis pipeline because errors and noise can affect the quality of collected data, preventing an accurate subsequent analysis. Several methods could be used for data cleaning according to the specific required task.

Data Integration and Transformation

Barbara Calabrese, University "Magna Graecia" of Catanzaro, Catanzaro, Italy

Introduction

Recent technological advances in high throughput biology, have generated vast amounts of omics data. Data integration and data transformation are two fundamental steps of biological data preprocessing. Specifically, data integration can refer to different levels. For example it regards the merging of data from multiple data stores. Careful integration can help reduce and avoid redundancies and inconsistencies in the resulting data set (Han, 2012). This can help improve the accuracy and speed of the subsequent data mining process. Data integration is not a simple task, but it poses several issues, such as entity identification problem, redundancy and inconsistencies in attribute or dimension. In the following paragraphs, a further discussion about different levels of data integration is reported.

In the data transformation, the data are transformed or consolidated so that the resulting mining process may be more efficient, and the patterns found may be easier to understand. The main methods for data transformation are illustrated in this contribution.

Data Integration

Data integration can occur at different levels. The integration of data of the same type (e.g., nucleotide sequence or protein sequence) enables the user to use a single interface to access all possible data for analysis. Moreover, the integration of data of different types for analysis allows a deeper understanding of biological phenomena. Specifically, data integration collectively analyses all datasets and builds a joint model that captures all datasets. Thus, data integration process is crucial for the advancements in genomics, proteomics, metabolomics and, generally speaking, biological research because a comprehensive understanding of a biological system can come only from a joint analysis of all omics layers (i.e., genome, proteome, metabolome, etc...) Wanichthanarak *et al.* (2015).

Data integration methodologies have to meet many computational challenges. These challenges arise owing to different sizes, formats and dimensionalities of the data being integrated, as well as owing to their complexity, noisiness, information content and mutual concordance (i.e., the level of agreement between datasets) Gomez-Cabrero *et al.* (2014).

Schemas Integration

As pointed before, the aim of data integration in bioinformatics is to establish automated and efficient methods to integrate large, heterogeneous biological datasets from multiple sources. Biological databases are geographically distributed and heterogeneous in terms of their functions, structures, data access methods and dissemination formats (Zhang *et al.*, 2011). According to their functions, databases can be categorized into different classes: (i) sequence databases, e.g., GenBank (Benson *et al.*, 2015), RefSeq (O'Leary *et al.*, 2016); (ii) functional genomics databases, e.g., ArrayExpress (Kolesnikov *et al.*, 2014); (iii) protein-protein interaction databases, e.g., DIP (Database of Interacting Proteins) (Salwinski *et al.*, 2004), IntAct (Orchard *et al.*, 2013); (iv) pathway databases, e.g., KEGG (Kyoto Encyclopedia of Genes and Genomes) (Kanehisa *et al.*, 2017); (v) structure databases, e.g., CATH (Sillitoe *et al.*, 2015; Dawson *et al.*, 2017); (vi) annotation databases, e.g., GO (Gene Ontology) (Ashburner *et al.*, 2000).

In Lapatas *et al.* (2015), computational solutions allowing users to fetch data from different sources, combine, manipulate and re-analyse them as well as being able to create new datasets, have been discussed. Specifically, general computational schemas used to integrate data in biology include data centralisation, federated databases, linked data, service-oriented integration.

Methodologies and Tools for Integrative Analysis

It is becoming evident that integrative analyses across multiple omic platforms are needed to understand complex biological systems. Over the past several years, enrichment analyses methods such as gene set enrichment analysis (GSEA) have been widely used to analyse gene expression data. These methods integrate biological domain knowledge (e.g., biochemical pathways, biological processes) with gene expression results (Gligorivic and Przulj, 2015).

Network-based analyses are used to study a variety of organismal and cellular mechanisms. Biological networks represent complex connections among diverse types of cellular components such as genes, proteins, and metabolites.

Correlation analysis is useful for omic data integration when there is a lack of biochemical domain knowledge and to integrate biological and other meta data (Gligorivic and Przulj, 2015).

Data Transformation

In data transformation, the data are transformed or consolidated into forms appropriate for mining. Strategies for data transformation include the following (Han, 2012):

- Smoothing, which works to remove noise from the data. Techniques include binning, regression, and clustering;
- Aggregation, where summary or aggregation operations are applied to the data;
- Normalization, where the attribute data are scaled so as to fall within a smaller range, such as -1.0 to 1.0 , or 0.0 – 1.0 ;
- Discretization, where the raw values of a numeric attribute (e.g., age) are replaced by interval labels (e.g., 0–10, 11–20, etc.) or conceptual labels (e.g., youth, adult, senior).

In the subsequent subparagraphs, the main normalization and discretization techniques are reported.

Normalization

Normalization is required to avoid that the data model is not influenced by high or low values and falls into small specified range (Purshit *et al.*, 2018). There are several normalization techniques, such as:

- Min-max normalization. The following equation (Eq. (1)) refers to min-max normalization:

$$v'_i = \frac{v_i - \text{Min}_A}{\text{Max}_A - \text{Min}_A} (\text{newMax}_A - \text{newMin}_A) + \text{newMin}_A \quad (1)$$

where A is the input array, v_i is the i -th input value, Min_A e Max_A are respectively minimum and maximum values in the input array A . newMax_A e newMin_A are 1 and 0 since the mapping of original values is being to range between 0 and 1.

- Zero mean normalization. The equation for this type of normalization is (Eq. (2)):

$$z = \frac{x - \mu}{\sigma} \quad (2)$$

where x is the value in an array, μ is the mean, σ is the standard deviation of the array.

- Normalization by decimal scaling. Decimal scaling is the method which provides the range between -1 and 1 , according to the following formula (Eq. (3)):

$$v'_i = \frac{V}{10^j} \quad (3)$$

v'_i is scaled value, V is the value in an array in i th position and j is the smallest integer as $\max(|v_i|) < 1$.

Discretization

Data discretization aims to map the real data into a typically small numbers of finite values in order to allow the application of algorithms that require discrete data as an input (Gallo *et al.*, 2016). Discretization techniques can be categorized based on how the discretization is performed, such as whether it uses class information. If the discretization process uses class information, then we say it is supervised discretization. Otherwise, it is unsupervised.

Data discretization refers also to data reduction. The raw data are replaced by a smaller number of interval or concept labels. This simplifies the original data and makes the mining more efficient. The resulting patterns mined are typically easier to understand. Moreover, discretized data show more robustness in the presence of noise. However this technique implies always a loss of information.

Closing Remarks

Data integration and data transformation are fundamental in the preprocessing stage of data analysis pipeline to achieve accurate mining results and a deeper understanding of biological phenomena. This contribution has presented the main approaches for data integration and the main data transformation techniques in biological context.

Introduction

Data reduction techniques can be useful to obtain a smaller dataset in volume, avoiding to lose in the reduced representation significant information of the original data. The aim is to generate and process subsequently a dataset more efficiently. Data reduction methods include dimensionality reduction, numerosity reduction, and data compression. In bioinformatics analysis, the application of data reduction techniques is essential in order: (i) to eliminate the irrelevant or noise features; (ii) to reduce storage requirements, computation time and resource usage and, (iii) to decrease the complexity of identification of the main features (Tchitchek, 2018; Prasartvit *et al.*, 2013).

In the following paragraphs the main methodologies for biological data reduction are presented and discussed.

Dimensionality Reduction

Dimensionality reduction is the process of reducing the number of random variables or attributes under consideration (Han, 2012; Meng *et al.*, 2016). Dimensionality reduction methods include wavelet transforms and Principal Components Analysis (PCA), which transform or project the original data onto a smaller space. Other approaches for dimension reduction for microarray data are based on Independent Component Analysis (ICA) (Aziz *et al.*, 2017). In the following subparagraphs, the main methodologies for biological data reduction are illustrated and discussed.

Linear Transformation

Linear transformations are applied to multivariate data to produce new datasets that are more meaningful or can be condensed into fewer variables (Semmlow, 2009). The data transformation used to produce new dataset is often a linear transformations that are easier to compute. A linear transformation can be represented as reported in Eq. 1:

$$y_i(t) = \sum_{j=1}^M w_{ij}x_j(t) \quad i = 1 \dots N \quad (1)$$

Where w_{ij} are constant coefficients that define the transformation. The two most used techniques for data reduction based on linear transformations are Principal Component Analysis (PCA) and Independent Component Analysis (ICA). In PCA, the aim is to transform the data set so as to produce a new set of variables (named principal components) that are uncorrelated. In ICA, the goal is to find new variables (named independent components), that are both statistically independent and non-Gaussian.

Principal Components Analysis

Principal Component Analysis (PCA) is considered a technique for reducing the number of variables without loss of information and for identifying new variables with greater meaning (Semmlow, 2009). PCA reduces data by geometrically projecting them onto lower dimensions, called principal components (Lever *et al.*, 2017). The first principal component is chosen to minimize the total distance between the data and their projection onto the principal component. The second (and subsequent) principal components are selected similarly, with the additional requirement that they are uncorrelated with all previous principal components. This requirement of no correlation means that the maximum number of principal components possible is either the number of samples or the number of features, whichever is smaller. The principal components selection process has the effect of maximizing the correlation between data and their projection. There are different ways of solving PCA. The most efficient algorithm uses Singular Value Decomposition (SVD) (Yao *et al.*, 2012).

In addition to being uncorrelated, the principal components are orthogonal and are ordered in terms of the variability they represent. Thus, the data size can be reduced by eliminating the weaker components, that is, those with low variance. The computation of principal components involves second order statistics that might not be always appropriate for biological data (Jolliffe, 2002).

Independent Component Analysis

Independent Component Analysis (ICA) is a technique that allows the separation of a mixture of signals into their different sources, by assuming non Gaussian signal distribution (Yao *et al.*, 2012). The ICA extracts the sources by exploring the independence underlying the measured data. Thus, it involves higher order statistics to recover statistically independent signals from

the observations of an unknown linear mixture. It turns out to be a technique more powerful than others, such as the Principal Component Analysis (PCA). The typical application of ICA is the “cocktail party problem”. In this situation, multiple people are speaking simultaneously within the same room. Their voices are recorded through multiple microphones, where the number of microphones are greater or equal to the number of speakers. Each microphone records a mixture of the voices of all speakers in the room. The application of ICA allows to recover the original signals produced by different speakers from recorded microphone signals (Hyvarinen and Oja, 2000).

Suppose that X is the input data matrix with dimension $[n \times p]$, where n is the number of samples and p is the number of measured variables or biological entities. The ICA generative model (i.e., a model that describes how the mixed signals are produced) is as follows (Eq. (2)):

$$X = AS \quad (2)$$

where A is the mixing matrix that indicates how the independent components (S) are linearly combined to build X (measured variables or signals). The model assumes that the mixed signals are the product of instantaneous linear combinations of the independent sources. The goal of the ICA is to recover the original signals only from the observations and consequently it is needed to construct an unmixing matrix, W which is the inverse matrix of the mixing matrix (Eq. (3)):

$$S = WX \quad (3)$$

The condition of independence implies the search for moments of superior order. These moments are null for a Gaussian variable. Two classical measures of gaussianity are kurtosis and negentropy. In Lee and Batzoglou (2003), the authors demonstrate that ICA methodologies outperform other leading methods, such as PCA for microarray data reduction.

Wavelet Transforms

In signal processing and analysis, a transform function permits to remapping the signal in order to provide more information than original. Fourier Transform (FT), for example, gives information about the different frequency components in the specific signal. Short-time Fourier Transform (STFT) is an example of time-frequency transform that provides information of the presence of various frequency components evolving time. The limit of STFT is that the analysis window frame is fixed. A more informative transform is represented by wavelet. Wavelet transforms (WT) in comparison to FT and STFT, offer the advantage of time frequency localisation of a signal by using windows of varying sizes and hence are capable of multi resolution analysis of signals. There are two types of wavelet transforms: continuous wavelet transforms (CWT) and discrete wavelet transforms (DWT).

A waveform of finite duration and zero average value is called a wavelet. WT is calculated using a mother wavelet function $\psi(t)$, by convolving the original signal $f(t)$ with the scaled and shifted version of the mother wavelet described by Eq. (4) where a is called the scaling parameter and b is called the translational parameter (Mallat, 2009).

$$Cab = \int_t f(t) \frac{1}{\sqrt{a}} \frac{\psi * (t - b)}{a} dt \quad (4)$$

Since continuous wavelet transforms are calculated at all possible scales and positions, they generate a large amount of data and require larger computation time. In discrete wavelet analysis, scales and positions are chosen based on powers of 2, called the dyadic scales. After discretization, the wavelet function is defined as given in Eq. (5):

$$\psi_{m,n}(t) = \frac{1}{\sqrt{2^m}} \psi * \frac{(t - nb_0 a_0^m)}{a_0^m} \quad (5)$$

where a_0 and b_0 are constants. The scaling term is represented as a power of a_0 and the translation term is a factor of a_0^m . Values of the parameters a_0 and b_0 are chosen as 2 and 1 respectively and is called as dyadic grid scaling.

The dyadic scaling scheme is implemented using filters developed by Mallat (1989). The original signal is filtered through a pair of one high pass filter $g(n)$ and one low pass filter $h(n)$, and then down sampled to get the decomposed signal through each filter which is half the length of the original signal. This process of filtering results in decomposition of the signal into different frequency components. The low frequency components are called *approximations* and high frequency components are called *details*. The dyadic scaling scheme is implemented using filters developed by Mallat (1989). This constitutes one level of decomposition, mathematically expressed as (see Eqs. (6) and (7)):

$$Y_{hp}(k) = \sum_n X(n)g(2k - n) \quad (6)$$

$$Y_{lp}(k) = \sum_n X(n)h(2k - n) \quad (7)$$

where $X(n)$ is the original signal, $h(n)$ and $g(n)$ are the sample sequences or impulse responses and $Y_{hp}(k)$ and $Y_{lp}(k)$ are the outputs of the high-pass and low-pass filters, respectively, after subsampling by 2. This procedure, known as sub-band coding, can be repeated for further decomposition. At every level, the filtering and subsampling result in half the number of samples (and hence half the time resolution) and half the frequency band spanned (and hence double the frequency resolution) (Saini and Dewan, 2016).

The usefulness lies in the fact that the wavelet transformed data can be truncated. A compressed approximation of the data can be retained by storing only a small fraction of the strongest of the wavelet coefficients (Liu, 2007). For example, all wavelet coefficients larger than some user-specified threshold can be retained. All other coefficients are set to 0. The work in Cannataro *et al.* (2001) presents a method for data compression based on wavelet transform.

Attribute Selection

Data sets for analysis may contain irrelevant and/or redundant attributes. Some of them can be very noisy and can cause errors in classification process. Moreover, they slope down the overall mining process. Attribute subset selection is a method of dimensionality reduction in which irrelevant, weakly relevant, or redundant attributes or dimensions are detected and removed (Han, 2012). Attribute selection reduces the data set size by removing irrelevant or redundant attributes (or dimensions), guaranteeing that the resulting probability distribution of the data classes is as close as possible to the original distribution obtained using all features/attributes. The appropriate selection increases the accuracy of the analysis and efficiency of the total process of data mining.

In the process of manual selection of attributes, the user decides which attributes should be eliminated. It is a subjective and time-consuming method.

Heuristic methods that explore a reduced search space are commonly used for attribute subset selection. Their strategy is to make a locally optimal choice in the hope that this will lead to a globally optimal solution. The choice of attributes is performed using tests of statistical significance, which assume that the attributes are independent of one another. Basic heuristic methods of attribute subset selection include stepwise forward selection, stepwise backward elimination, combination of the previous methods and decision tree induction (Han, 2012).

Numerosity Reduction

Numerosity reduction techniques replace the original data by alternative, smaller forms of data representation. These techniques may be parametric or nonparametric (Han, 2012).

For parametric methods, a model is used to estimate the data, so that typically only the data parameters need to be stored, instead of the actual data. Regression and log-linear models are examples of parametric methods. Nonparametric methods for storing reduced representations of the data include histograms, clustering, sampling, and data cube aggregation.

Parametric Data Reduction: Regression

Regression and log-linear models can be used to approximate the given data. In (simple) linear regression, the data are modeled to fit a straight line. For example, a random variable, y (called a response variable), can be modeled as a linear function of another random variable, x (called a predictor variable), with the Eq. (8):

$$y = b + wx \quad (8)$$

where the variance of y is assumed to be constant. The coefficients, w and b (called regression coefficients), specify the slope of the line and the y -intercept, respectively. These coefficients can be solved by the method of least squares, which minimizes the error between the actual line separating the data and the estimate of the line. Multiple linear regression is an extension of (simple) linear regression, which allows a response variable, y , to be modeled as a linear function of two or more predictor variables (Eq. (9)):

$$y = b_0 + b_1x_1 + b_2x_2 \quad (9)$$

Log-linear model approximates discrete multidimensional probability distributions. This model estimates the probability of each point (tuple) in a multi-dimensional space for a set of discretized attributes, based on a smaller subset of dimensional combinations.

Non Parametric Data Reduction: Histograms, Clustering and Sampling

Histogram is a popular data reduction technique. It divides data into buckets and store average (sum) for each buckets.

Clustering techniques partition the objects into groups, or clusters, so that objects within a cluster are “similar” to one another and “dissimilar” to objects in other clusters. Similarity is commonly defined in terms of how “close” the objects are in a space, based on a distance function. The “quality” of a cluster may be represented by its diameter, the maximum distance between any two objects in the cluster. Centroid distance is an alternative measure of cluster quality and is defined as the average distance of each cluster object from the cluster centroid (denoting the “average object,” or average point in space for the cluster).

In data reduction, the cluster representations of the data are used to replace the actual data. The effectiveness of this technique depends on the data’s nature. It is much more effective for data that can be organized into distinct clusters than for smeared data.

Sampling techniques should create representative samples. A sample is representative, if it has approximately the same property (of interest) as the original set of data. Using a representative sample will work almost as well as using the full datasets (Han, 2012). There are several sampling techniques:

- Simple random sampling: every sample of size n has the same chance of being selected. It uses random numbers. Specifically, if the selected item cannot be selected again, this method is called sampling without replacement; in the sampling with replacement, items can be picked up more than once for the sample – not removed from the full dataset once selected.
- Stratified sampling: data are splitted into several partitions (strata); then draw random samples from each partition. Each strata may correspond to each of the possible classes in the data. The number of items selected from each strata is proportional to the strata size.
- Cluster sampling: is a technique in which clusters of data are identified and included in the sample.

Data Compression

Data compression includes all methods that are applied in order to obtain a reduced or “compressed” representation of the original data. If the original data can be reconstructed from the compressed data without any information loss, the data reduction is called lossless, otherwise the data reduction is called lossy. In (Hosseini, 2016) a review about proteomic and genomic data compression methods is reported.

Proteomic Data Compression

In Nevill-Manning and Witten (1999), the CP (Compress Protein) scheme is proposed, as the first protein compression algorithm, which employs probability to weight all contexts with the maximum of a certain length, based on their similarity to the current context. The XM (eXpert Model) method, presented in Cao *et al.* (2007), encodes each symbol by estimating the probability based on previous symbols. When a symbol is recognized as part of a repeat, the previous occurrences are used to find that symbol's probability distribution; then, it is encoded using arithmetic coding. “Approximate repeats” are utilized in the methods presented in Hategan and Tabus (2004). The ProtComp algorithm exploits approximate repeats and mutation probability for amino-acids to build an optimal substitution probability matrix including the mutation probabilities). Exploiting the “dictionary” is taken into consideration in the methods proposed in Hategan and Tabus (2007) and Daniels *et al.* (2013). In Hategan and Tabus (2007), the ProtCompSecS method is presented, which considers the encoding of protein sequences in connection with their annotated secondary structure information. This method is the combination of the ProtComp algorithm (Hategan and Tabus, 2004) and a dictionary based method, which uses the DSSP (Dictionary of Protein Secondary Structure) database. A heuristic method is introduced in Hayashida *et al.* (2014), that exploits protein domain compositions. In this method, a hyper-graph is built for the proteome, based on evolutionary mechanisms of gene duplication and fusion.

Genomic Data Compression

Genomic data compression methods are grouped in reference-free methods that are based only on the characteristics of the target sequences and reference-based methods, that exploit a set of references sequence (Lee *et al.*, 2007).

The basic idea of reference-free genomic sequence compression is exploiting structural properties, e.g., palindromes, as well as statistical properties of the sequences. The first algorithm which was specifically proposed for genomic sequences compression is biocompress (Grumbach and Tahi, 1993). In this algorithm, that is based on the Ziv and Lempel compression method (Ziv and Lempel, 1977), factors (repeats) and complementary factors (palindromes) in the target sequence are identified and then they are encoded using the length and the position of their earliest occurrences.

In DNA Compact algorithm (Gupta and Agarwal, 2011), the target sequence is first converted into words in a way that A, T, C and G bases are replaced with A, C, <space>A and <space>C, respectively, i.e., the four symbol space is transformed into a three symbol space. In the second phase, the obtained sequence is encoded by WBTC (Word Based Tagged Code).

The GeCo algorithm (Pratas *et al.*, 2016) exploits a combination of context models of several orders for reference-free, as well as for reference-based genomic sequence compression. In this method, extended finite-context models (XFCMs) are introduced and cache-hashes are employed. The cache-hash uses a fixed hash function to simulate a specific structure and takes into consideration only the last hashed entries in memory.

Reference-based genome sequence compression are based on the analysis of the similarity between a target sequence and a (set of) reference sequence(s). For this aim, the target is aligned to the reference and the mismatches between these sequences are encoded. Since the decompressor has access to the reference sequence(s), the reference-based methods obtain high compression rates (Zhu *et al.*, 2013; Wandelt *et al.*, 2014; Deorowicz and Grabowski, 2011). The DNazip algorithm (Christley *et al.*, 2009) was presented for compressing James Watson's genome, considering the high similarity between human genomes, implying that only the variation is required to be saved. In this method, variation data are considered in three parts: (i) SNPs (single nucleotide polymorphisms), which are saved as a position value on a chromosome and a single nucleotide letter of the polymorphism; (ii)

insertions of multiple nucleotides, which are saved as position values and the sequence of nucleotide letters to be inserted; and (iii) deletions of multiple nucleotides, which are saved as position values and the length of the deletion.

In the RLZ algorithm (Kuruppu *et al.*, 2010), each genome is parsed into factors, using the LZ77 approach (Ziv and Lempel, 1977). Then, the compression is done relative to the reference sequence, which is used as a dictionary.

A statistical compression method, GReEn (Genome Re-sequencing Encoding), is proposed in Pinho *et al.* (2012). In this method, the probability distribution of each symbol in the target sequence is estimated using an adaptive model (the copy model), which assumes that the symbols of the target sequence are a copy of the reference sequence, or a static model, relying on the frequencies of the symbols of the target sequence.

The GDC (Genome Differential Compressor) method (Deorowicz and Grabowski, 2011), is based on the LZ77 approach and considers multiple genomes of the same species. In this method, a number of extra reference phrases, that are extracted from other sequences, along with an LZ-parsing for detection of approximate repeats are used. The GDC 2 method (Deorowicz *et al.*, 2015) is an improved version of the GDC that considers short matches after some longer ones. It is worth pointing out that both the GDC and GDC 2 methods support random access to an individual sequence.

The ERGC (Efficient Referential Genome Compressor) method, based on a divide and conquer strategy, is proposed in Saha and Rajasekaran (2015). In this method, first, the reference sequence and the target sequence are divided into some parts with equal sizes; then, an algorithm, which is based on hashing, is used to find one-to-one maps of similar regions between the two sequences. Finally, the identical maps and dissimilar regions of the target sequence, are fed into the PPMD compressor for further compression of the results.

The iDoComp algorithm (Ochoa *et al.*, 2015) consists of three phases. In the first phase, named mapping generation, the suffix arrays are exploited to parse the target sequence into the reference sequence. In the second phase, the consecutive matches, which can be merged together to form an approximate match, are found and used for reducing the size of mapping. Finally, in the third phase, named entropy encoding, an adaptive arithmetic encoder is used for further compression of the mapping and then generation of the compressed file.

The DNA-COMPACT method (Li *et al.*, 2013) can be used for both reference-free and reference-based genome compression. In a first phase, an adaptive mechanism is presented which firstly, considers a sliding window for the subsequences of the reference sequence; then, it searches for the longest exact repeats in the current fragment of the target sequence, in a bi-directional manner. In the second phase, the non-sequential contextual models are introduced and then their predictions are synthesized exploiting the logistic regression model.

The CoGI method (Xie *et al.*, 2015) can be used for reference-free as well as for reference-based genome compression. Considering the latter case, at first, a proper reference genome is selected using two techniques based on base co-occurrence entropy and multi-scale entropy. Next, the sequences are converted to bit-streams, using a static coding scheme, and then the XOR (exclusive or) operation is applied between each target and the reference bit-streams. In the next step, the whole bit-streams are transformed into bit matrices like binary images (or bitmaps). Finally, the images are compressed exploiting a rectangular partition coding method.

Concluding Remarks

There are many data reduction methods, which can be applied to exploratory data analysis of a single data set, or integrated analysis of a pair or multiple data sets. In this contribution the main methods for dimensionality reduction, numerosity reduction and data compression have been discussed, specifically for proteomic and genomic data.

Dimensionality Reduction

Introduction

In the last 20 years the advances in high performance computing technologies, with more and more powerful and fast computers for data storage and processing, and in the engineering field, with the assembly of more and more sophisticated sensors, determined a huge development of “high resolution” offering new possibilities for scientific knowledge. We are now in the “big-data” era and new methodologies have emerged to perform real time descriptive and predictive analysis on massive amount of data, in order to formulate intelligent informed decisions. The word “big data” refers to a high volume of heterogeneous data formed by continuous or discontinuous information stream. It is a class of data sets so large that it becomes difficult to analyse using the standard methods of data processing. The problems of such data include collection, storage, search, sharing, transfer, visualization and analysis. Big data involves increasing volume, that is, amount of data; velocity, that is speed at which data is in and out; and variety, that is, range of data types and sources, indeed it has been characterized as 3Vs (Laney, 2001). But another V has been added and this 4th V refers to veracity, i.e. reliability of the accumulated data. For these reasons big data has unique features that are not shared by the traditional data sets: massive sample size, high-dimensionality and intrinsic heterogeneity.

This is particularly true for the biomedical/bioinformatics domain, that has experienced a drastic advance since the advent of complete genome sequences. In particular, in Stephens *et al.* (2015) the authors compared genomics with three other major generators of big data: Twitter, You-Tube, and astronomy, in terms of annual storage space required. Twitter requires 117 PB (Petabyte or 1 million GB), whereas You-Tube and astronomy require 1 EB (Exabyte or 1 billion GB) and 12 EB, respectively. Genomics, which is only a part of bioinformatics data, requires 240 EB per year! The authors further estimated that between 100 million and as many as 2 billion human genomes could be sequenced by the year 2025, representing 45 orders of magnitude growth in 10 years and far exceeding the growth in the 3 other big data domains. This explains the fundamental role of dimensionality reduction for the analysis of big data to extract meaningful knowledge. Dimensionality reduction techniques aim at finding and exploiting low-dimensional structures in high-dimensional data to overcome the “curse of dimensionality” and reduce computation and storage burden.

Curse of dimensionality is a term coined by Bellman (1961) and refers to the problem caused by the rapid increase in volume associated with adding extra dimensions to a (mathematical) space. Indeed a local neighbourhood in higher dimensions is no longer local, i.e. the sparsity increases exponentially given a fixed amount of data points, hence to achieve the same accuracy or resolution and a statistically significant result, much larger data sets are needed.

For example, 100 equispaced sample points in a unit interval have 0.01 distance between them; to maintain the same distance among points in a 10-dimensional unit hypercube would require 10^{20} sample points!

Background/Fundamentals

Dimensionality reduction can be categorized into two main components: feature extraction and feature selection.

Feature extraction projects the original input data in a space of lower dimension. Each new variable is a linear or non-linear combination of the original variables, containing basically the same information as the input data. Three main representatives of this class are Principal Component Analysis (PCA) (Pearson, 1901; Hotelling, 1933; Jolliffe, 2002), Fisher Discriminant Analysis, also called Linear Discriminant Analysis (LDA) (Fisher, 1936; Mika *et al.*, 1999; Duda *et al.*, 2000) and the ISOMetric feature MAPping (ISOMAP) (Tenenbaum *et al.*, 2000). PCA and LDA are both linear techniques, whereas ISOMAP is a non linear one.

Feature selection only keeps the most relevant variables from the original dataset to construct a model having the “best” predictive power. In the context of regression, representative methods of this class are subset selection techniques, i.e., best subset selection and stepwise selection (Miller, 2002). However, recently sparse learning based methods have received considerable attention due to their good performance and their theoretical robustness; a pioneer technique is the Least Absolute Shrinkage and Selection Operator (LASSO) introduced by Tibshirani in 1996 (Tibshirani, 1996).

Table 1 summarizes some common symbols used throughout this survey. Bold upper-case letters are used for matrices (e.g. $\mathbf{A}$) and bold lower-case letters for vectors (e.g., $\mathbf{a}$). The (i,j) -th entry of $\mathbf{A}$ is represented by a_{ij} and the transpose of $\mathbf{A}$ by $\mathbf{A}'$. For any vector $\mathbf{a} = (a_1, \dots, a_n)'$ its 2-norm is defined as $\|\mathbf{a}\|_2 = \sqrt{\sum_{i=1}^n a_i^2}$, and its 1-norm is $\|\mathbf{a}\|_1 = \sum_{i=1}^n |a_i|$. $\mathbf{I}_k \in \mathbb{R}^{k \times k}$ is the identity matrix of dimension k and $\mathbf{1}_k \in \mathbb{R}^{k \times 1}$ is a vector of dimension k of all ones.

Methodologies

PCA

PCA uses a linear and orthonormal transform to project p input variables, possibly correlated, onto a set of linearly uncorrelated variables called principal components (PCs). The PCs preserve most of the information given by variances and correlations/

Table 1 Symbols

Notation	Definition or description
n	number of samples
p	number of variables/features
$\mathbf{x} = (x_1, \dots, x_p)' \in R^{p \times 1}$	random vector of dimension p representing variables
$\mathbf{x}_1, \dots, \mathbf{x}_n \in R^{p \times 1}$	n independent samples of $\mathbf{x}$
$\mathbf{X} = \begin{pmatrix} \mathbf{x}_1' \\ \vdots \\ \mathbf{x}_n' \end{pmatrix} \in R^{n \times p}$	data matrix with element x_{ij} being variable j of sample i
$m_j = \frac{1}{n} \sum_{i=1}^n x_{ij}$	sample mean of variable x_j , $j=1, \dots, p$
$\mathbf{m} = (m_1, \dots, m_p) = \frac{1}{n} \mathbf{X}' \mathbf{1}_n \in R^{p \times 1}$	vector of sample means
$\mathbf{S} = \frac{1}{n-1} (\mathbf{X} - \mathbf{1}_n \mathbf{m}') (\mathbf{X} - \mathbf{1}_n \mathbf{m}')' \in R^{p \times p}$	sample covariance matrix based on samples $\mathbf{x}_1, \dots, \mathbf{x}_p$

covariances of the original variables, and their number is less or equal than p . Moreover the PCs are the principal axes of a p -dimensional ellipsoid that fits the data. The first largest principal axis of such ellipsoid will then define the direction of maximum statistical variation. The second principal axis maximizes statistical variation, subject to being orthogonal to the first, and so on. Let's see in detail how PCA works.

Consider a data matrix $\mathbf{X} \in R^{n \times p}$ and assume that variables have been centred, i.e. $m_j = 0$, $j=1, \dots, p$.

In this case the sample covariance $\mathbf{S} = \frac{1}{n-1} \mathbf{X}' \mathbf{X}$.

The projection matrix $\mathbf{A} \in R^{p \times m}$, $m \leq p$, is given by m p -dimensional vectors $\mathbf{a}_k \in R^{p \times 1}$ (the loadings), $k=1, \dots, m$, that map each $\mathbf{x}_i \in R^{p \times 1}$, $i=1, \dots, n$ to a m dimensional vector $\mathbf{z}_i = (z_1^i, \dots, z_m^i)' \in R^{m \times 1}$ (the PCs), $i=1, \dots, n$ with $z_k^i = \mathbf{x}_i' \mathbf{a}_k$, $k=1, \dots, m$, such that the new variables z_k , $K=1, \dots, m$, account for the maximum variability in $\mathbf{X}$, with each $\mathbf{a}_k$, $k=1, \dots, m$ constrained to be a unit vector ($\|\mathbf{a}_k\|_2 = 1$).

Thus the first loading vector $\mathbf{a}_1 \in R^{p \times 1}$ must satisfy

$$\begin{aligned} \mathbf{a}_1 &= \arg \max_{\|\mathbf{a}\|_2 = 1} \left\{ \sum_{i=1}^n (z_1^i)^2 \right\} = \arg \max_{\|\mathbf{a}\|_2 = 1} \left\{ \sum_{i=1}^n (\mathbf{x}_i' \mathbf{a})^2 \right\} \\ &= \arg \max_{\|\mathbf{a}\|_2 = 1} \{ \|\mathbf{Xa}\|^2 \} = \arg \max \left\{ \frac{\mathbf{a}' \mathbf{X}' \mathbf{Xa}}{\mathbf{a}' \mathbf{a}} \right\} \end{aligned}$$

It can be shown that, since $\mathbf{X}' \mathbf{X}$ is symmetric, the maximum is reached for its maximum eigenvalue $\lambda_{\max}$ when $\mathbf{a}_1$ is $\mathbf{v}_{\max}$ the corresponding eigenvector.

Once the first component has been determined, the k -th component, $k \geq 2$, can be found by considering the residual of the projection of data on $\mathbf{a}_1, \dots, \mathbf{a}_{k-1}$, i.e.

$$\hat{\mathbf{x}}_i = \mathbf{x}_i - \sum_{s=1}^{k-1} (\mathbf{x}_i' \mathbf{a}_s) \mathbf{a}_s, \quad i=1, \dots, n \Leftrightarrow \hat{\mathbf{X}}_k = \mathbf{X} - \sum_{s=1}^{k-1} (\mathbf{Xa}_s) \mathbf{a}_s'$$

and then finding the loading vector $\mathbf{a}_k$ that maximizes the variance of the new data

$$\arg \max_{\|\mathbf{a}\|_2 = 1} \{ \|\hat{\mathbf{X}}_k \mathbf{a}\|^2 \} = \arg \max \left\{ \frac{\mathbf{a}' \hat{\mathbf{X}}_k' \hat{\mathbf{X}}_k \mathbf{a}}{\mathbf{a}' \mathbf{a}} \right\}$$

Playing a bit with linear algebra, it is possible to show that $\mathbf{a}_k$ is the k -th eigenvector of $\mathbf{X}' \mathbf{X}$ corresponding to the k -th largest eigenvalue.

Thus the full principal components decomposition of $\mathbf{X}$ is given by

$$\mathbf{Z} = \mathbf{XA}, \mathbf{Z} \in R^{n \times p}$$

where $\mathbf{A}$ is a matrix of dimension $p \times p$ whose columns are the eigenvectors of $\mathbf{X}' \mathbf{X}$. From this it follows that

$$\text{cov}(\mathbf{Z}) = \mathbf{A}' \text{cov}(\mathbf{X}) \mathbf{A} = \mathbf{A}' \mathbf{S} \mathbf{A} = \frac{\mathbf{\Lambda}}{n-1}, \quad \text{where} \quad \mathbf{X}' \mathbf{X} = \mathbf{A} \mathbf{\Lambda} \mathbf{A}'$$

is the eigenvalue-eigenvector decomposition of $\mathbf{X}' \mathbf{X}$ and $\mathbf{\Lambda}$ is its eigenvalue matrix. This means that the PCs are decorrelated, but if data follow a normal distribution, the PCs are independent. Moreover it follows that

$$\text{Tr}(\mathbf{S}) = \frac{1}{n-1} \sum_{i=1}^p \lambda_i = \text{Tr}(\text{cov}(\mathbf{Z}))$$

i.e., the total variation in the data $\mathbf{X}$ equals the total variation in the PCs and the proportion of variation explained by each PC is $\lambda_s / (\sum_{i=1}^p \lambda_i)$, $s=1, \dots, p$. Obviously to reduce the original dimension p to m , with $m \leq p$, we can consider only the first m eigenvectors to project the original data, i.e.

$$\mathbf{Z}_m = \mathbf{XA}_m$$

and, by construction, this score matrix $\mathbf{A}_m$ maximizes the variance in the original data that has been preserved, while minimising the residual of the projection. In this case the total variance explained by the first m components will be $(\sum_{i=1}^m \lambda_i) / (\sum_{i=1}^p \lambda_i)$.

The PCA can also be built using the Singular Value Decomposition (SVD) (Golub and Van Loan, 1996) of input matrix $\mathbf{X}$, that decomposes $\mathbf{X}$ as

$$\mathbf{X} = \mathbf{U}(\boldsymbol{\Sigma})\mathbf{V}', \mathbf{U} \in \mathbb{R}^{n \times r}, \mathbf{V} \in \mathbb{R}^{p \times r}, (\boldsymbol{\Sigma}) = \text{diag}(\sigma_1, \dots, \sigma_r) \in \mathbb{R}^{r \times r}$$

being r the rank of $\mathbf{X}$. From this it follows the spectral decomposition of $\mathbf{X}$

$$\mathbf{X}'\mathbf{X} = \mathbf{V}(\boldsymbol{\Sigma})^2\mathbf{V}'$$

The PCs are therefore given by

$$\mathbf{Z} = \mathbf{X}\mathbf{V} = \mathbf{U}(\boldsymbol{\Sigma})\mathbf{V}'\mathbf{V} = \mathbf{U}(\boldsymbol{\Sigma})$$

and the variance of the scores for the k -th PC is $\sigma_k^2 / (n - 1)$.

A truncated $n \times m$ score matrix, $m \leq r$, $\mathbf{Z}_m$ can be obtained by considering only the first m largest singular values and their singular vectors

$$\mathbf{Z}_m = \mathbf{U}_m(\boldsymbol{\Sigma})_m$$

It can be shown that $\mathbf{Z}_m$ gives the best possible rank m approximation to $\mathbf{Z}$, in the sense of the difference between the two having the smallest possible Frobenius norm (Eckart and Young, 1936; Householder and Young, 1938; Gabriel, 1978).

An important question is the choice of m , i.e. the number of PCs. Different techniques exist, such as the Cumulative Percentage of Total Variation, the Kaiser's rule, the Scree plot, tests of hypothesis, cross-validation or bootstrapping. The first three are ad hoc rules-of-thumb, whose justification is mainly based on intuition and on the fact that they work in practise. Tests of hypothesis require distributional assumptions that often data don't satisfy. Computationally intensive methods, such as cross validation or bootstrapping are too expensive for high dimensional data. A detailed description of the possible proposals and all the mathematical and statistical properties of PCA can be found in Jolliffe (2002).

The derivation and properties of PCs are based on the eigenvalue-eigenvector decomposition of the covariance matrix. In practise, it is more common to standardize the variables $\mathbf{x}$ and define PCs as the eigenvectors of the correlation matrix. A major argument for using correlation is the sensitivity of the PCs derived from covariance matrix to the units of measurements of each element of $\mathbf{x}$. If the variances of elements of $\mathbf{x}$ differ too much each other, then variables with the largest variance will tend to dominate the first few PCs. On the contrary for correlation matrices the standardized variates are a-dimensional and can be happily combined to give PCs.

Fisher Linear Discriminant

Fisher Linear Discriminant/LDA, uses a linear transform to reduce the dimension seeking directions that are efficient for discrimination when it is known how data divide into K classes. The idea is to build a projection that preserves as much of the class discriminatory information as possible. Fig. 1 shows the conceptual difference between PCA and LDA.

Assume that $\mathbf{x}_1, \dots, \mathbf{x}_n$ are distributed in K classes, n_1 in C_1 , n_2 in $C_2, \dots, n_K$ in C_K , with $n_1 + \dots + n_K = n$. The idea is to obtain a transformation of $\mathbf{X}$ projecting the samples onto a hyperplane with dimension $K - 1$.

Consider first the case with two classes, i.e. $K=2$. In this case the hyperplane is a line and this means to obtain the following n scalars

$$y_i = \mathbf{w}'\mathbf{x}_i, \quad \mathbf{w} \in \mathbb{R}^{p \times 1}, \quad i = 1, \dots, n$$

where the optimal projection $\mathbf{w}$ is the one that maximizes the separability of the scalars.

Fig. 1 PCA and LDA. Reproduced from Sebastianraschka. Available at: https://sebastianraschka.com/Articles/2014_python_lda.html.

A measure of the separation between the projected points is the difference of the sample means. The mean vector of each class in $\mathbf{x}$ and $\mathbf{y} = (y_1, \dots, y_n)'$ feature space is:

$$\mathbf{m}_i = \frac{1}{n_i} \sum_{\mathbf{x} \in C_i} \mathbf{x}, \quad \text{and} \quad \tilde{\mathbf{m}}_i = \frac{1}{n_i} \sum_{\mathbf{x} \in C_i} \mathbf{w}' \mathbf{x} = \mathbf{w}' \mathbf{m}_i \quad i = 1, 2$$

It follows that the distance between the projected means is

$$|\tilde{\mathbf{m}}_1 - \tilde{\mathbf{m}}_2| = |\mathbf{w}'(\mathbf{m}_1 - \mathbf{m}_2)|$$

and this difference can be made as large as wanted merely by scaling $\mathbf{w}$. Of course, to obtain a good separation of y_i , $i = 1, \dots, n$, it is important to take into account the variability of data within the classes. The solution proposed by Fisher is to maximize a function that represents the difference between the means, normalized by a measure of the within-class variability, or the so-called *scatter*. For each class the scatter, an equivalent of the variance, is defined as

$$\tilde{s}_i^2 = \sum_{y \in C_i} (y - \tilde{\mathbf{m}}_i)^2, \quad i = 1, 2$$

$\tilde{s}_i$ measures the variability within class C_i after projecting it on the $\mathbf{y}$ -space. Thus $\tilde{s}_1 + \tilde{s}_2$ measures the variability within the two classes at hand after projection, hence it is called *within-class scatter* of the projected samples. The Fisher linear discriminant is defined as the linear function $\mathbf{w}'\mathbf{x}$ that maximizes the criterion function

$$J(\mathbf{w}) = \frac{|\tilde{\mathbf{m}}_1 - \tilde{\mathbf{m}}_2|^2}{\tilde{s}_1^2 + \tilde{s}_2^2}$$

Therefore, the maximization looks for a projection where samples from the same class are projected very close to each other and, at the same time, the projected means are as far apart as possible. To obtain $J(\cdot)$ as an explicit function of $\mathbf{w}$, it is useful to define the scatter matrices $\mathbf{S}_i$, $i = 1, 2$, and $\mathbf{S}_W$ by

$$\mathbf{S}_i = \sum_{\mathbf{x} \in C_i} (\mathbf{x} - \mathbf{m}_i)(\mathbf{x} - \mathbf{m}_i)' \quad \text{and} \quad \mathbf{S}_W = \mathbf{S}_1 + \mathbf{S}_2$$

It easily follows

$$\tilde{s}_i^2 = \sum_{\mathbf{x} \in C_i} (\mathbf{w}'\mathbf{x} - \mathbf{w}'\mathbf{m}_i)^2 = \mathbf{w}'\mathbf{S}_i\mathbf{w} \quad i = 1, 2 \quad \text{and} \quad \tilde{s}_1^2 + \tilde{s}_2^2 = \mathbf{w}'\mathbf{S}_W\mathbf{w}$$

Similarly

$$(\tilde{\mathbf{m}}_1 - \tilde{\mathbf{m}}_2)^2 = (\mathbf{w}'\mathbf{m}_1 - \mathbf{w}'\mathbf{m}_2)^2 = \mathbf{w}'\mathbf{S}_B\mathbf{w} \quad \text{with} \quad \mathbf{S}_B = (\mathbf{m}_1 - \mathbf{m}_2)(\mathbf{m}_1 - \mathbf{m}_2)'$$

$\mathbf{S}_W$ is called the *within-class scatter matrix* and is proportional to the sample covariance matrix for the pooled p -dimensional data. $\mathbf{S}_B$ is called the *between-class scatter matrix* and its rank is at most one being the outer product of two vectors. Moreover for any $\mathbf{w}$, $\mathbf{S}_B\mathbf{w}$ is in the direction of $\mathbf{m}_1 - \mathbf{m}_2$. In terms of $\mathbf{S}_W$ and $\mathbf{S}_B$, the criterion function $J(\cdot)$ can be written as

$$J(\mathbf{w}) = \frac{\mathbf{w}'\mathbf{S}_B\mathbf{w}}{\mathbf{w}'\mathbf{S}_W\mathbf{w}}$$

and the vector $\mathbf{w}$ that maximizes it, satisfies

$$\mathbf{S}_B\mathbf{w} = \lambda \mathbf{S}_W\mathbf{w} \tag{1}$$

which is a generalized eigenvalue problem. If $\mathbf{S}_W$ is not singular then Eq. (1) can be rewritten as a common eigenvalue problem

$$\mathbf{S}_W^{-1}\mathbf{S}_B\mathbf{w} = \lambda \mathbf{w}$$

whose solution can be immediately written as

$$\mathbf{w} = \mathbf{S}_W^{-1}(\mathbf{m}_1 - \mathbf{m}_2)$$

being $\mathbf{S}_B\mathbf{w}$ in the direction of $\mathbf{m}_1 - \mathbf{m}_2$, and the classification has been converted from a p -dimensional problem to a more manageable one-dimensional one.

Suppose now to have K classes. In this case there will be $K - 1$ discriminant functions and the projection is from a p -dimensional space to a $(K - 1)$ -dimensional space ($p \geq K$), i.e.

$$\mathbf{y}_i = \mathbf{W}'\mathbf{x}_i, \quad \mathbf{y}_i \in R^{K-1 \times 1}, \quad \mathbf{W} = [\mathbf{w}_1, \dots, \mathbf{w}_{K-1}] \in R^{p \times K-1}; \quad i = 1, \dots, n$$

The generalization for the within-class scatter matrix is

$$\mathbf{S}_W = \sum_{i=1}^K \mathbf{S}_i, \quad \text{where} \quad \mathbf{S}_i = \sum_{\mathbf{x} \in C_i} (\mathbf{x} - \mathbf{m}_i)(\mathbf{x} - \mathbf{m}_i)' \quad \text{and} \quad \mathbf{m}_i = \frac{1}{n_i} \sum_{\mathbf{x} \in C_i} \mathbf{x}$$

The between-class scatter matrix is defined as

$$\mathbf{S}_B = \sum_{i=1}^K n_i(\mathbf{m}_i - \mathbf{m})(\mathbf{m}_i - \mathbf{m})', \quad \text{with} \quad \mathbf{m} = \frac{1}{n} \sum_{\mathbf{x}} \mathbf{x} = \frac{1}{n} \sum_{i=1}^K n_i \mathbf{m}_i \quad \text{total mean}$$

Fig. 2 LDA and PCA on the Iris data.

Similarly, the mean vectors and the scatter matrices for the projected samples $\mathbf{y}_i$ are defined as

$$\tilde{\mathbf{m}} = \frac{1}{n} \sum_{i=1}^K n_i \tilde{\mathbf{m}}_i, \quad \tilde{\mathbf{m}}_i = \frac{1}{n_i} \sum_{\mathbf{y} \in C_i} \mathbf{y}$$

$$\tilde{\mathbf{S}}_W = \sum_{i=1}^K \sum_{\mathbf{y} \in C_i} (\mathbf{y} - \tilde{\mathbf{m}}_i)(\mathbf{y} - \tilde{\mathbf{m}}_i)', \quad \tilde{\mathbf{S}}_B = \sum_{i=1}^K n_i (\tilde{\mathbf{m}}_i - \tilde{\mathbf{m}})(\tilde{\mathbf{m}}_i - \tilde{\mathbf{m}})'$$

and it is easy to show that

$$\tilde{\mathbf{S}}_W = \mathbf{W}' \mathbf{S}_W \mathbf{W} \quad \text{and} \quad \tilde{\mathbf{S}}_B = \mathbf{W}' \mathbf{S}_B \mathbf{W}$$

The optimal transformation matrix $\mathbf{W}$ is the one that maximizes the ratio of the between-class scatter to the within-class scatter. This measure gives origin to the following criterion

$$J(\mathbf{W}) = \frac{|\tilde{\mathbf{S}}_B|}{|\tilde{\mathbf{S}}_W|} = \frac{|\mathbf{W}' \mathbf{S}_W \mathbf{W}|}{|\mathbf{W}' \mathbf{S}_B \mathbf{W}|}$$

It can be shown that the columns of $\mathbf{W}$ are the generalized eigenvectors that correspond to the largest eigenvalues in

$$\mathbf{S}_B \mathbf{w}_i = \lambda_i \mathbf{S}_W \mathbf{w}_i$$

Because $\mathbf{S}_B$ is the sum of K matrices of rank at most 1, and only $K - 1$ are independent, $\mathbf{S}_B$ is of rank at most $K - 1$. Thus, no more than $K - 1$ of the eigenvalues are non-zero, and the desired weight vectors correspond to these non-zero eigenvalues. Once the data have been projected, a full classifier can be created using the Bayesian decision theory.

Fig. 2 shows the IRIS data (Fisher, 1936) and their projection by LDA and PCA:

ISOMAP

ISOMAP is a dimensionality reduction method that combines the major algorithmic features of PCA and Multi Dimensional Scaling (MDS), i.e. computational efficiency, global optimality, and asymptotic convergence guaranteed, with the flexibility to

learn a broad class of non linear manifolds. In mathematics a manifold is a topological space that is locally Euclidean (i.e., around every point, there is a neighbourhood that is topologically the same as the open unit ball in R^n). An example of manifold is the Earth. We know it is round but on the small scales that we see, the Earth looks flat. In general, any object that is nearly “flat” on small scales is a manifold.

ISOMAP exploits geodesic paths for nonlinear dimensionality reduction, indeed it finds the map that preserves the global, nonlinear geometry of the data by maintaining the geodesic manifold inter-point distances. Recall that in the original sense a geodesic was the shortest route between two points on the Earth’s surface, then the term has been generalized to include measurements in much more general mathematical spaces.

The crucial point is the estimation of the geodesic distance between distant points, given only input-space distances (euclidean). For neighbouring points, input space distance provides a good approximation to geodesic distance. For distant points, geodesic distance can be approximated by adding up a sequence of short hops between neighbouring points. These approximations are computed efficiently by finding shortest paths in a graph with edges connecting neighbouring data points.

ISOMAP algorithm has the following three steps:

- identification of which points are neighbours on the manifold M , based on the euclidean distances $d_X(\mathbf{x}_i, \mathbf{x}_j)$ between pairs of points $\mathbf{x}_i, \mathbf{x}_j$ in the input space $X = R^{p \times 1}$. Two simple methods are to connect each point to all points within some fixed radius ε , or to consider all of its K nearest neighbours. These neighbourhood relations are represented as a weighted graph G over the data points, with edges of weight $d_X(\mathbf{x}_i, \mathbf{x}_j)$ between neighbouring points;
- estimation of the geodesic distances $d_M(\mathbf{x}_i, \mathbf{x}_j)$ between all pairs of points on the manifold M by the computation of their shortest path distances $d_G(\mathbf{x}_i, \mathbf{x}_j)$ in the graph G ;
- application of the classical MDS to the matrix of graph distances $D_G = \{d_G(\mathbf{x}_i, \mathbf{x}_j)\}$, constructing an embedding of the data in a d -dimensional Euclidean space $Y = R^{d \times 1}$ that best preserves the manifolds estimated intrinsic geometry. The coordinate vectors $\mathbf{y}_i$ for points in Y are chosen to minimize the cost function

$$E = \|\tau(D_G) - \tau(D_Y)\|_F \quad (2)$$

where D_Y denotes the matrix of euclidean distances $\{d_Y(\mathbf{y}_i, \mathbf{y}_j) = \|\mathbf{y}_i - \mathbf{y}_j\|_2\}$ and $\|A\|_F = \sqrt{\sum_i \sum_j a_{ij}^2}$ is the Frobenius norm. The operator τ converts distances to inner products which uniquely characterize the geometry of the data in a form that supports efficient optimization. τ is defined as

$$\tau(D) = -\frac{\mathbf{H}\mathbf{S}\mathbf{H}}{2}$$

with

$$\mathbf{S} = (s_{ij}) = (D_{ij}^2) \quad \text{and} \quad \mathbf{H} = (h_{ij}) = \left(\delta_{ij} - \frac{1}{N} \right), \quad \delta_{ij} = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases}$$

$\mathbf{S}$ is the matrix of squared distances and $\mathbf{H}$ is the centering matrix. It can be shown that the global minimum of Eq. (2) is achieved by setting the coordinates $\mathbf{y}_i$ to the top d eigenvectors of the matrix $\tau(D_G)$. Note that, as for PCA, the true dimensionality of the data can be estimated from the decrease in error as the dimensionality of Y is increased.

ISOMAP recovers asymptotically the true dimensionality and geometric structure of a strictly larger class of nonlinear manifolds. Indeed it can be shown that as the number of data points increases, the graph distances $d_G(\mathbf{x}_i, \mathbf{x}_j)$ provide increasingly better approximations to the intrinsic geodesic distances $d_M(\mathbf{x}_i, \mathbf{x}_j)$, becoming arbitrarily accurate in the limit of infinite data (Tenenbaum *et al.*, 2000).

Fig. 3 shows the Swiss Roll data and their projection by ISOMAP:

Subset Selection

Aim of the regression is to model and quantify the relationship between groups of variables, i.e.

$$\mathbf{y} = f(\mathbf{x}), \quad \mathbf{y} = (y_1, \dots, y_q)' \in R^{q \times 1}, \quad \mathbf{x} = (x_1, \dots, x_p)' \in R^{p \times 1}$$

where the independent variables $\mathbf{x}$ are called predictors, regressors or explanatory variables and the dependent ones $\mathbf{y}$ are called responses. Regression consists of two steps: estimation of the existing connection and prediction of new values.

The most basic type of regression and commonly used predictive analysis is the multiple linear regression (Jobson, 1991). Multiple linear regression models the relation between a scalar response variable y , i.e. $q=1$, and one or more explanatory variables $\mathbf{x}$ by linear predictor functions whose unknown parameters are estimated from the data. Given a dataset $(y_i, \mathbf{x}_i)_{i=1, \dots, n}$ of n samples of $(y, \mathbf{x})$ a linear regression model assumes the following relationship

$$y_i = \beta_0 + \mathbf{x}_i' \boldsymbol{\beta} + \varepsilon_i \quad i = 1, \dots, n, \quad \boldsymbol{\beta} \in R^{p \times 1}$$

where $\boldsymbol{\varepsilon} = (\varepsilon_1, \dots, \varepsilon_n)'$ is the noise or the error term that captures all other factors which influence the dependent variable y_i other than the predictors $\mathbf{x}_i$. It is assumed independent from $\mathbf{x}$, with zero mean and covariance $\sigma^2 I_p$.

Fig. 3 3D Nonlinear Swiss Roll data and 2D Linear Manifold.

If $n \geq p$ and $\text{rank}(X) = p$, β can be efficiently estimated by the least squares method and used for future prediction. In the case these conditions are not verified, it is necessary to consider alternatives by replacing ordinary least squares fitting with some other fitting procedures that improve the prediction accuracy and the model interpretability. Indeed by “treating” the irrelevant features in some way, a model that is more easily interpreted can be obtained.

However, the selection of the “most informative” regressors from a larger set of observable variables to predict a particular quantity of interest y is an important problem independent from the conditions on n and p . First of all, it may be necessary because it is expensive to measure the variable y and it is hoped to be able to predict it with sufficient accuracy from other variables which can be measured cheaply. Unless the true form of the relationship between the x and y variables is known, it will be necessary for the data used to select the variables and to calibrate the relationship to be representative of the conditions in which the relationship will be used for prediction. Secondly, the variance of the predicted values increases monotonically with the number of variables used in the prediction. Indeed as more variables are added to a model we are “trading off” reduced bias against an increased variance. If a variable has no predictive value, then its inclusion just increases the variance. If the addition of a variable doesn’t reduce the biases significantly, then the increase in prediction variance may exceed the benefit from bias reduction.

Two classes of methods can be taken into account: subset selection and shrinkage. The subset selection identifies a subset of the p predictors that it is believed to be related to the response, then least squares on the reduced set of variables is performed. The shrinkage fits a model involving all p predictors, but the estimated coefficients are shrunk towards zero relative to the least squares estimates. This shrinkage (also known as regularization) has the effect of reducing variance and can also perform variable selection.

The subset selection divides into two procedures: best subset and stepwise model selection. The best subset selection consists of the following three steps:

- Let M_0 denote the null model, which contains no predictors. This model simply predicts the sample mean for each observation.
- For $k = 1, \dots, p$:
 - a) Fit all $\binom{p}{k}$ models that contain exactly k predictors.
 - b) Pick the best among these $\binom{p}{k}$ models, and call it M_k . Here best is defined as having the smallest Residual Sum of Squares (RSS), or equivalently largest R^2 .
- Select a single best model from among $M_0, \dots, M_p$ using cross-validated prediction error, Mallows C_p , Akaike Information Criterion (AIC), Bayesian Information Criterion (BIC), or adjusted R^2 .

Obviously, for computational reasons, best subset selection is infeasible with very large p . Moreover, the larger the search space, the higher the chance of finding models that look good on the training data, even though they might not have any predictive power on future data. Thus an enormous search space can lead to overfitting and high variance of the coefficient estimates. For both of these reasons, stepwise methods, which explore a restricted set of models, are attractive alternatives. Stepwise methods are of two types: forward and backward.

Forward stepwise selection begins with a model containing no predictors, and then adds predictors to the model, one-at-a-time, until all of the predictors are in the model. In particular, at each step the variable that gives the greatest additional improvement to the fit is added to the model. In particular

- Let M_0 denote the null model, which contains no predictors.
- For $k=0, \dots, p$:
 - a) Consider all $p-k$ models that augment the predictors in M_k with one additional predictor.
 - b) Choose the best among these $p-k$ models, and call it M_{k+1} . Here best is defined as having smallest RSS or highest R^2 .
- Select a single best model from among $M_0, \dots, M_p$ using cross-validated prediction error, Mallows C_p , AIC, BIC, or adjusted R^2 .

It is important to stress that it is not guaranteed that the procedure finds the best possible model out of all 2^p models containing subsets of the p predictors.

The term stepwise regression is often used to mean an algorithm proposed by [Efroymson \(1960\)](#). This is a variation on forward selection. After each variable (other than the first) is added to the set of selected variables, a test is made to see if any of the previously selected variables can be deleted without appreciably increasing the residual sum of squares. As with forward selection, there is no guarantee that the Efroymson algorithm will find the best-fitting subsets, though it often performs better than forward selection when some of the predictors are highly correlated. The algorithm incorporates its own built-in stopping rule.

Like forward stepwise selection, backward stepwise selection provides an efficient alternative to best subset selection. However, unlike forward stepwise selection, it begins with the full least squares model containing all p predictors, and then iteratively removes the least useful predictor, one-at-a-time.

- Let M_p denote the null model, which contains all p predictors.
- For $k=p, \dots, 1$:
 - a) Consider all k models that contain all but one of the predictors in M_k , for a total of $k-1$ predictors.
 - b) Choose the best among these k models, and call it M_{k-1} . Here best is defined as having smallest RSS or highest R^2 .
- Select a single best model from among $M_0, \dots, M_p$ using cross-validated prediction error, Mallows C_p , AIC, BIC, or adjusted R^2 .

Like forward stepwise selection, the backward selection approach searches through only $1 + p(p+1)/2$ models, and so can be applied in settings where p is too large to apply best subset selection. Also backward stepwise selection is not guaranteed to yield the best model containing a subset of the p predictors. Backward selection requires that the number of samples n is larger than the number of variables p (so that the full model can be fit). In contrast, forward stepwise can be used even when $n < p$, and so is the only viable subset method when p is very large.

As an alternative to subset selection in the case of $p > n$, there exist the shrinkage methods that fit a model containing all p predictors using a technique that constrains the coefficient estimates, or equivalently, that shrinks the coefficient estimates towards zero, and in some cases performs variable selection. This shrinking of the coefficient estimates can significantly reduce their variance, also if it increases the bias. However the total error estimate is lower than the one from the least square fitting.

A very recent alternative is the Lasso. The lasso coefficients, $\hat{\beta}_{\lambda}^L$, minimize the quantity

$$\min_{\beta} \sum_{i=1}^n \left(y_i - \beta_0 - \sum_{j=1}^p x_{ij} \beta_j \right)^2 + \lambda \sum_{j=1}^p |\beta_j|$$

Lasso shrinks the coefficient estimates towards zero, as with ridge regression, but the use of an ℓ_1 penalty instead of a ℓ_2 penalty has the effect of forcing some of the coefficient estimates to be exactly equal to zero when the tuning parameter is sufficiently large. Hence, much like subset selection, the lasso performs variable selection and yields sparse model, that is, models that involve only a subset of the variables.

Future Directions

Machine learning and statistics for high dimensional data have been the most utilized tools for data analysis. Large scale data existed well before the big data era, particularly in bioinformatics, and different techniques have been successfully used to analyse both small scale as well as large scale. However, big data poses more challenges on the traditional learning methods in terms of velocity, variety, and incremental data. Traditional learning methods usually embed iterative processing and complex data dependency among operations consequently, they cannot be used to perform fast processing on massive data. Accomplishing the goal of data analysis will clearly require integration of different expertises, large-scale machine learning systems, and a computing infrastructure that can support flexible and dynamic queries to search for patterns over very large collections in very high dimensions.

Closing Remarks

The enormous quantity of data produced in every fields, social, economic, medical, cyber security, just to cite some, offered new challenges to scientists in order to produce significant knowledge. Machine learners, mathematicians and statisticians put a lot of effort in investigating new methodologies or extending the old ones to deal with the “curse of dimensionality” in the “big data era”. Indeed data analysis today is not an unsophisticated activity carried out by hand; it is much more ambitious and is now producing quite sophisticated objects. This is why dimensionality reduction is the hottest topic in data science today, aiming at building simpler and more comprehensible models, improving data mining performance, and helping prepare, clean, and understand data.

PCA, LDA and feature selection in linear regression models represents the basis knowledge each scientist should have.

Kernel Machines: Introduction

Italo Zoppis and Giancarlo Mauri, University of Milan-Biocca, Milan, Italy

Introduction

Kernel methods are a class of machine learning algorithms implemented for many different inferential tasks and application areas (Smola and Schölkopf, 1998; Shawe-Taylor and Cristianini, 2004; Schölkopf and Burges, 1999). The main idea of these techniques is to map the observed examples (i.e., *training set*) into a new representation space (known as *feature space*), where object properties can be extracted more easily, and linear algorithms are exploited to find relationships that are difficult to identify within the original *pattern space*.

Importantly, it is not necessary to know the map which provides the new input representation, rather by reformulating the algorithm in a way that only requires the knowledge of inner products between the input data, one can evaluate a particular *kernel function* without explicitly expressing the embedding.

In this context, a kernel is a mathematical function, satisfying specific properties, that can be interpreted as a similarity measure between data items. Therefore, when a learning algorithm is adapted to access input only through inner products then, in that procedure, inner products can be replaced by a kernel function. This is the well known *kernel trick* which provides an implicit input transformation into the new space of representation.

Moreover, the interpretation of kernels as similarity measures has important consequences. First, as we will see, it motivates the design of specific kernels for particular inferential problems and data types. Then, it gives us the possibility to apply this approach in all distance-based (or dissimilarity-based) methods, as for example in Pekalska and Duin (2005), Ramakrishnan et al. (2010), Cava et al. (2014). In this article we will describe the kernel approach, following this interpretation.

The Kernel Function

Machine learning algorithms aim to identify functional dependencies within the observed data (i.e., experience or training set) to make useful inferences, using the dependencies that have been learned. In other words, machine learning allows one to build predictive models from observed data, and to apply these models to infer the properties of new items.

The inference models, trained using the kernel approach, are based on an interesting and powerful property. They allow to obtain new data representations for the training patterns, by embedding such observations, into a new *feature space* (Fig. 1). Then, in the new feature space, using techniques from optimization, mathematical analysis and statistics, one can extrapolate interesting properties, which will be useful for providing the required inference for new data.

Inference often takes the form of classification, which is probably one of the oldest and most studied machine learning activities. Classification aims to identify to which of a set of categories a new observation belongs, on the basis of a set of examples containing observations whose category labels (i.e., group membership) are known. A typical classification within healthcare is, for example, the determination of whether new subjects can be discriminated from patients (or cases) or classified as healthy (controls), according to a set of previously sampled attribute values, see for example, Chinello et al. (2014), Cava et al. (2013a,b). The discrimination is provided by a classification algorithm, which takes a set of labeled examples as input (i.e., patient records

Fig. 1 Kernels use nonlinear maps to embed input patterns in a feature space where linear predictive models are applied.

with their associated labeled groups), and returns a *trained* model, generally defined by a set of fitted parameters. Suppose, for example, that we are given the following training set.

$$\mathcal{T} = \{(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)\} \in \mathcal{X} \times \mathcal{Y}$$

We refer to the objects denoted by x_i as patterns, while the $y_i \in \mathcal{Y}$ – the response variables, are generally called labels. The training set $\mathcal{T}$ of all pairs (x_i, y_i) represents past observations, whereas the collection of new examples, for which we would like to guess new labels, $\hat{y}_i \in \mathcal{Y}$, is generally called the *test set*. In other words, our aim is to generalize the correspondences (x_i, y_i) , using a function h which can be defined on all possible objects $\mathcal{X}$, and generate labels from the set of all possible labels $\mathcal{Y}$. The label predicted for a new test pattern, x , would then be $\hat{y} = h(\hat{x})$.

Notice that, no particular assumption is made about the nature of $\mathcal{X}$ (and $\mathcal{Y}$). The set $\mathcal{X}$ can be any collection of structured objects, such as graphs, strings, tree, etc. In this respect, it is important to emphasize that structured data are considered to be composed by simpler components combined into a more complex items. Frequently, this combination involves the recursive usage of simpler objects of the same type, e.g., [Comellas et al. \(2004\)](#).

It is not difficult now to intuitively see how h should behave to provide good generalization over all observations from $\mathcal{X}$. Indeed, any $x \in \mathcal{X}$ that is close to an observed input x_i , should have (target) label $y = h(x)$ close to the observed $y_i = h(x_i)$. Thus, the difficulty of this task consists in defining what we mean by “close” both within $\mathcal{X}$ and within $\mathcal{Y}$. (More precisely, we need to quantify the input similarities in $\mathcal{X}$ and the cost of incorrectly assigning outputs within $\mathcal{Y}$. We call this the loss function, which considers the sum of the costs (or losses) of all mistakes made, when we consider a particular possible solution $h(x_i)$ and applies it to all known items $(x_i, y_i) \in \mathcal{T}$. For instance we can choose):

$$\mathcal{L}(h(x_i), y_i) = \sum_{i=1}^N \|h(x_i) - y_i\| \quad (1)$$

Measuring similarity in $\mathcal{Y}$ can be quite easy, for example we could define a zero-one “loss function” such as,

$$\mathcal{L}(y, y_i) = I(y \neq y_i), \quad (2)$$

where I is the indicator function. On the other hand, quantifying similarities in $\mathcal{X}$ can be more difficult, in particular when one has to consider the different nature of objects in $\mathcal{X}$. Kernel methods introduced an interesting and targeted approach to this aim. It is required that, such a measure (let us denote it with k), should be defined as

$$k : \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{R}, \quad (3)$$

$$(x_i, x_j) \mapsto k(x_i, x_j).$$

Moreover, k should satisfy the property that

$$k(x_i, x_j) := \langle \Phi(x_i), \Phi(x_j) \rangle_{\mathcal{H}} \quad (4)$$

for all $x_i, x_j \in \mathcal{X}$ (The notation $\langle \cdot, \cdot \rangle$ represents an inner product. This operation is used to abstract the properties of a dot product that takes two equal-length sequences of numbers (usually, coordinate vectors) and returns a single number.). The function $\Phi : \mathcal{X} \rightarrow \mathcal{H}$ in [Eq. \(4\)](#) can be thought as a new representation for the patterns $x \in \mathcal{X}$ in the new feature space $\mathcal{H}$. The advantage offered by the new representation is considerable. Due to this mapping, we can easily transform linear models into nonlinear models. Furthermore, the input domain does not necessarily need to be a vector space.

A symmetric function k , as defined by [Eq. \(4\)](#), for which the property expressed in [Eq. \(4\)](#) holds, is called a kernel function. Another advantage offered by [Eq. \(4\)](#) is expressed by the representation of $k(x_i, x_j)$ in terms of the inner product $\langle \Phi(x_i), \Phi(x_j) \rangle$ in $\mathcal{H}$. Due to this fact (i.e., *inner product representation*), we can think of the kernel as a measure of similarity between input patterns. Whenever [Eq. \(4\)](#) holds, one has an important mathematical tool. Since there exists a feature space $\mathcal{H}$, and a map Φ from $\mathcal{X}$ to the inner product feature space $\mathcal{H}$ (Hilbert space.), the inner product between $\Phi(x_i)$ and $\Phi(x_j)$ in $\mathcal{H}$ can be computed in terms of the kernel evaluations $k(x_i, x_j)$ in $\mathcal{X} \times \mathcal{X}$. Moreover, given a kernel k and a set $S = \{x_1, \dots, x_n\}$, we can define a corresponding *Gram matrix* (sometimes called the *Kernel matrix*) whose entries are expressed as follows.

$$G_{ij} = \langle \Phi(x_i), \Phi(x_j) \rangle_{\mathcal{H}} = k(x_i, x_j). \quad (5)$$

Generally, the only information received by a machine learning algorithm, from the training set, comes from the Gram matrix and its related output values. In other words, all the information that a kernel-based learning algorithm can obtain about training data is provided by the kernel matrix together with any labeled examples. For this reason the Gram matrix can be considered as an information bottleneck that must transmit enough information about the data for the algorithm to be able to perform its task. The Kernel function ([Eq. \(4\)](#)) and the corresponding Gram matrix ([Eq. \(5\)](#)) are both the core and the critical parts of kernel methods. They imply that the observed patterns never have to be expressed explicitly in $\mathcal{H}$, as long as these data only appear as inner products in the considered formulations, i.e., the implemented machine learning algorithm. Since it is possible to construct a function $k(x, x')$, such that $k(x, x') = \langle \Phi(x), \Phi(x') \rangle_{\mathcal{H}}$, then during learning, every time we need to compute $\langle \Phi(x), \Phi(x') \rangle_{\mathcal{H}}$, we can just evaluate $k(x, x')$ - i.e., we don't need to actually apply and express the function $\Phi(x)$. In this way, we say that the transformation would exist only “implicitly”.

A fundamental and natural question, now, is to consider under what circumstances a function k may represent an inner product in order to be considered a valid kernel. It can be proved that every symmetric positive definite function k (i.e., satisfying *Mercer conditions*) represents a valid inner product in some feature space, as defined by [Eq. \(4\)](#), see e.g., [Vapnik \(1995\)](#), [Mercer \(1909\)](#).

Examples of Kernels

The choice of a particular kernel k is not straightforward. k should be chosen carefully, as it is the core of the generalization process. Each choice of kernel will define a different type of feature space and the resulting inference algorithm will perform differently. Moreover, since a kernel can be thought as a measure of similarity, this choice can also be informed by domain expertise, as domain experts already know the actual similarities between objects in their respective contexts. The following examples provide kernel functions that can be broadly applied to various situations. More application-specific kernels will be discussed in the following paragraph.

- Polynomial kernel

$$k(\mathbf{x}, \mathbf{z}) = (\mathbf{x}'\mathbf{z})^d \quad (6)$$

which, for $d=2$, squares the product between the two vectors $\mathbf{x}=(x_1, x_2)$ and $\mathbf{z}=(z_1, z_2)$. In this case, extending the equation, we get

$$\begin{aligned} (\mathbf{x} \cdot \mathbf{z})^2 &= (x_1 z_1 + x_2 z_2)^2 \\ &= (x_1^2 z_1^2 + x_2^2 z_2^2 + 2x_1 z_1 x_2 z_2) \\ &= \langle (x_1, x_2, \sqrt{2}x_1 x_2), (z_1, z_2, \sqrt{2}z_1 z_2) \rangle \\ &= \langle \Phi(\mathbf{x}), \Phi(\mathbf{z}) \rangle \end{aligned} \quad (7)$$

The above example shows a typical situation, in all those circumstances e.g., pattern recognition, where even though the input examples $\mathbf{x}$ and $\mathbf{z}$ exist in a dot product space (i.e., $\mathfrak{R}^2$), we may still want to consider more general similarity measure by applying the map defined as

$$\Phi(x_1, x_2) = (x_1^2, x_2^2, \sqrt{2}x_1 x_2). \quad (8)$$

The function defined in Eq. (8) transforms the data in a higher dimensional space, embedding the input from a two dimensional space in a three-dimensional space. Notice that, the kernel function k in Eq. (7) corresponds to the inner product between two three-dimensional vectors expressed as the new representation, $\Phi(x_1, x_2)$. In other words, the inner product $\langle \Phi(\mathbf{x}), \Phi(\mathbf{z}) \rangle$ in $\mathfrak{R}^3$ can be easily obtained, in a totally equivalent way, by evaluating the function $(\mathbf{x} \cdot \mathbf{z})^2 \in \mathfrak{R}^2$, i.e., by using the kernel over $\mathcal{X} \times \mathcal{X}$, without explicitly re-writing the data using $\Phi(x_1, x_2)$. As expressed above, one can use the kernel trick to substitute inner products with kernels, whenever the selected function, k , gives rise to a positive definite matrix, $K_{ij}=k(x_i, x_j)$. This requirement ensures the existence of a mapping in some feature space, for which the representation $k(x, z)=\langle \Phi(\mathbf{x}), \Phi(\mathbf{z}) \rangle$ definitely holds. In general, if we had use a higher exponent, we can virtually embed the two vectors in a much higher dimensional space at a very low computational cost.

- Gaussian kernel also known as radial basis function. Gaussian kernels are one the most widely applied and studied kernels in literature. They are defined as follows

$$\begin{aligned} k(\mathbf{x}, \mathbf{z}) &= \exp\left(-\frac{\|\mathbf{x} - \mathbf{z}\|^2}{2\sigma^2}\right) \\ &= \exp\left(-\frac{\mathbf{x}^T \mathbf{x} - 2\mathbf{x}^T \mathbf{z} + \mathbf{z}^T \mathbf{z}}{2\sigma^2}\right). \end{aligned} \quad (9)$$

Here $\sigma > 0$ controls the flexibility of the kernel. Small values of σ allow classifiers to adapt any label, this way risking overfitting (See, e.g., [Cherkassky and Ma, 2004](#)) for setting the model parameters in order to obtain a good generalization performance.) We can observe that, in the feature space, the images of all points have norm equal to 1, as $k(x, z)=\exp(0)=1$. Moreover, the feature space can be chosen in such a way that all the images lie within a single orthant, since all the inner products between mapped points are positive.

Application-Specific Kernel

The capability to deal with different data is one of the advantages provided by kernel methods. The kernel representation $k(x_i, x_j) := \langle \Phi(x_i), \Phi(x_j) \rangle_{\mathcal{H}}$ does not assume any specific nature for the patterns x_i, x_j in the input domain $\mathcal{X}$, permitting the kernel to work with every data type our inference may require.

In particular, when input patterns are not defined as vectors (e.g., strings, trees, and graphs), kernels provide a general approach to making vector-based algorithms applicable (using input transformations) to all input data structures. This is a typical situation in real-world problems, where data can be “complex” structures, in some specific form. In these situations, it may be difficult to represent such data as vectors, and even when a vector-based representation is given, i.e., to apply the available vector-based

algorithms, part of information of the original patterns may be irretrievably lost, therefore reducing the discriminative power of the inference mechanism.

Moreover, since the kernel can be interpreted as a similarity measure, when the input structures are typical of some specific domain (for example, bio-sequences, images, or hypertext documents), it is also possible reveal which input data features are most relevant to the problem being considered. Hence, in these cases, the choice and the design of a specific kernel should be discussed together with domain experts, as they know the actual similarities between objects, and can help to properly define a kernel-based similarity measure.

Kernel for Strings

String algorithms and, in particular, string comparison algorithms are key topics in bioinformatics. Comparing DNA sequences can be indicative, for example, in the study of genetic variations with the aim whether two different DNA samples are from the same person, or whether genetic mutations may be critical for particular pathologies.

Measuring the similarity between sequences is therefore a very important task, and has become an essential tool for string comparison. Many approaches can be considered as referring to different ways of counting the sub-strings that two original strings have in common. Typical examples can be found in [Lodhi et al. \(2002\)](#), [Haussler \(1999\)](#). The standard idea is simple: the more sub-strings two strings have in common, the more similar they are. This quantity is generally referred as a *spectrum kernel*, and can be formulated as follows

$$k(s_i, s_j) = \sum_{q \in ((\Sigma))^n} \#(q \subset s_i) \cdot \#(q \subset s_j), \quad (10)$$

where $\#(q \subset s_i)$ is the frequency of sub-string $q \in ((\Sigma))^n$ in s_i . The kernel in [Eq. \(10\)](#) counts common sub-strings of length n in the two strings s_i and s_j . The advantage of this simple formulation is its fast computational time i.e., $O(|s_i| + |s_j|)$, where $|s|$ is the length of a string s .

The spectrum kernel has been extended in several ways, for example, by weighting the occurrences of sub-strings depending on how they are distributed within the original input. In this case, the kernel also takes into account the presence of gaps introduced to maximize the similarity of the sub-strings: see, for example, [Gordon et al. \(2003\)](#), [Rousu and Shawe-Taylor \(2005\)](#).

Kernel for Documents

Document analysis is certainly a challenging area of research within the machine learning community ([Joachims, 1998](#); [Yang and Liu, 1999](#)). A problem that most attracted the attention of researchers was the comparison and classification of the content of different documents (i.e., automatic assignment of a random document to one or more classes.). (Another important problem is the *document summarization* which refers to the process of extracting or generating shortened content from one or various sources, e.g., [Mamakis et al. \(2012\)](#)). Even in this case, the identification of appropriate similarity measures has had immediate results for many practical tasks, such as the office automation.

Significant results in this area have been obtained in Information Retrieval (IR) studies, which have provided the most commonly used representation to evaluate the content of documents. This representation is actually known as the Vector Space Model (VSM) (or bag-of-words) see, e.g., [Zhang et al. \(2010\)](#). The main idea of this method, can be given by introducing the following preliminary definitions.

Definition 4.1: (Bag). A Bag is a collection in which repeated elements are allowed.

Definition 4.2: (Words). Words are any sequence of letters from the basic alphabet separated by punctuation or spaces.

Definition 4.3: (Dictionary). A Dictionary can be defined by a predetermined set of terms.

Definition 4.4: (Corpus). Sometimes only those words belonging to the set of documents being processed are considered. In this case, we refer to this big collection of text (documents) as the corpus, and the set of terms occurring in the corpus as the dictionary.

Following the above terminology, a document can be viewed as a bag-of-words, and can be represented by a vector where each element is associated with one word from the dictionary. More formally,

$$(\text{tf}_d(t_1), \text{tf}_d(t_2), \dots, \text{tf}_d(t_n)), \in \mathfrak{R}^n \quad (11)$$

where $\text{tf}_d(t_i)$ is the frequency of the term t_i in the document d . In this way, we can consider the mapping $\Phi : d \rightarrow \Phi(d) \in \mathfrak{R}^n$ that represents a document as a point in a vector space of dimension n , which is the size of the dictionary. Typically, $\Phi(d)$ is a vector with many elements or features, and in many problems we can find more features than document examples within the training set. However, for a particular document, we have a sparse representation in which only a few elements have non zero entries.

Extending the representation in expression (11), we can define the following matrix.

$$D = \begin{pmatrix} \text{tf}(d_1, t_1) & \dots & \text{tf}(d_1, t_n) \\ \vdots & \ddots & \vdots \\ \text{tf}(d_n, t_1) & \dots & \text{tf}(d_n, t_n) \end{pmatrix} \quad (12)$$

The matrix D defined in Eq. (12) is known as a document-term matrix. Its rows are indexed by the documents of the corpus and its columns are indexed by the words of the text (terms). Hence, the (i, j) th value of D gives the frequency of term t_j in document d_i . Notice that, in IR, we can also find the so called term-document matrix, that is, the transpose D' of the document-term matrix defined in (12). With this definition, we can finally formalize the vector space kernel, as follows.

Definition 4.5: (Vector Space Kernel). Let us consider the matrix K defined as $K = DD'$. This matrix leads to the definition of the corresponding vector space kernel given by

$$k(d_1, d_2) = \langle \Phi(d_1), \Phi(d_2) \rangle = \sum_{j=1}^n \text{tf}(d_1, t_j) \text{tf}(t_j, d_2). \quad (13)$$

One problem with the above definition is that the ordering of the words is completely ignored. This is clearly a critical feature, since in most natural languages this circumstance modifies the semantics of the sentences. In addition, inferential aspects of several important tasks (e.g., speech recognition or short message classification), may be compromised if the relationship between words in the corpus is not taken into account. To address this problem, the vector space model has been extended by considering different ways to introduce semantic considerations in the formulation of the kernel (Shawe-Taylor and Cristianini, 2004).

Kernel for Graphs

Graph theory is a rich environment of powerful abstract techniques that allow modeling of several types of problems, both natural and human-made, ranging from biology to sociology (Mason and Verwoerd, 2007).

It is in this context that a recent focus in *machine learning* (Mitchell, 1997; Kolaczyk, 2014; Witten et al., 2011; Marsland, 2011) has been to extend traditional problems to systems of complex interactions, and more generally, to networks (Getoor and Taskar, 2007; Bansal et al., 2002). In this case, traditional algorithms may not only benefit from the information provided by relationships between instances (Zoppis and Mauri, 2008), but could even fail to achieve adequate performance when relational data are not properly supplied to a classification system.

A graph provides an abstract representation of the relationships among the elements of a set. Formally, we refer to a graph as $G = (V, E)$, where V is the set of elements (i.e., nodes or vertices) and E is the set of relationships between pairs of elements (i.e., edges). We use the notation $|V|$ to denote the number of nodes, and $|E|$ to denote the number of edges in the graph G . If u and v are two nodes and there is an edge from u to v , then we write that $(u, v) \in E$, and we say that v is a *neighbor* of u ; and u and v are adjacent.

The challenge of proposing a definition for a proper graph kernel is to find a suitable measure that captures a particular graph structure and, at the same time, is efficient to evaluate. For example, an elegant formulation, known as the *random-walk graph* kernel, can be found in Gartner et al. (2003), Kashima et al. (2003). To give a proper formulation for this kernel, let us consider the direct product (tensor product) of graphs, defined as a graph $G_x(G_1, G_2) = (V_x, E_x)$ whose vertices and edges are given as follows (See also Imrich and Klavzar, 2000.)

$$V_x = \{(v_1, w_1) : v_1 \in V, w_1 \in W, \text{Label}(v_1) = \text{Label}(w_1)\} \quad (14)$$

$$E_x = \{(v_1, w_1), (v_2, w_2) \in V_x \times V_x : (v_1, v_2) \in E, (w_1, w_2) \in F, \text{Label}(v_1, v_2) = \text{Label}(w_1, w_2)\}$$

where (V, E) and (W, F) are respectively, the vertices and the edges of the graphs $G_1 = (V, E)$ and $G_2 = (W, F)$. Using definition (14), the random-walk kernel can be defined as

$$k(G, G') = \sum_{i,j=1}^{|V_x|} \left[\sum_{k=0}^{\infty} \lambda_k A_x^k \right]_{i,j} \quad (15)$$

where A_x is the adjacency matrix of the product graph in (14). The sum in Eq. (15) converges for a suitable choice of the weights $\lambda_0, \lambda_1, \lambda_2, \dots$ (Gartner et al., 2003).

Kernel Composition

One of the attractiveness of kernel methods is due to the closure properties which kernels possess. This property can be summarized by the following proposition.

Proposition 1.: Let k_1, k_2 and k_3 be kernels over $\mathcal{X} \times \mathcal{X}$, $\mathcal{X} \subset \mathbb{R}^n$, $f(\cdot)$ a real-valued function on $\mathcal{X}$, $\Phi : \mathcal{X} \rightarrow \mathbb{R}^n$, B a positive semi-definite $n \times n$ matrix, and $p(x)$ a polynomial with positive coefficients. Then the following functions are kernels.

1. $k(x, z) = k_1(x, z) + k_2(x, z)$
2. $k(x, z) = \alpha k_1(x, z)$
3. $k(x, z) = k_1(x, z) + k_2(x, z)$
4. $k(x, z) = f(x)f(z)$
5. $k(x, z) = k_3(\Phi(x), \Phi(z))$
6. $k(x, z) = x' B z$
7. $k(x, z) = p(k_1(x, z))$
8. $k(x, z) = \exp(k_1(x, z))$

While the above property can be formally proven, from an applicative point of view, the importance of this result lies in the possibility of creating new kernels using already defined kernel functions. In this way, we can get more complex kernels from simple building blocks by simply applying a number of successive main operations.

This approach also has an important theoretical consequence: it provides a formal tool by which it is possible to show that new functions actually possess the property of being a kernel, i.e., of showing they are semi-positive defined functions. Often, this way of defining new kernel functions provides enough information for users to build suitable kernels for particular applications.

Kernel Algorithms

Many machine learning algorithms can be implemented in such a way that input patterns can be accessed only through inner product operations, using the representation $k(x_i, x_j) = \langle \Phi(x_i), \Phi(x_j) \rangle_{\mathcal{H}}$. Such algorithms are said to employ kernels, since the pairwise inner products can be computed directly from the original pattern space using the kernel function $k(x_i, x_j)$. In such a situation, a nonlinear version of a particular inference model can be easily obtained by simply replacing the inner products with the kernel k . This is called the kernel trick.

As an example, let us consider the case where the inference algorithm has to evaluate norms of vectors in the feature space. This computation, can be formulated in the following simple but important way

$$\|\Phi(x)\|_{\mathcal{H}} = \sqrt{\langle \Phi(x), \Phi(x) \rangle} = \sqrt{k(x, x)}. \quad (16)$$

The example in Eq. (16) shows that, despite the apparent impossibility of the evaluation of $\Phi(x)$, we can calculate this quantity by substituting the inner product with the kernel function k . Many well-known learning algorithms have been “kernelized” and have provided successful results in scientific disciplines such as bioinformatics, natural language processing, computer vision and robotics. Just to mention a few well known fundamental machine learning problems, we can refer to the following examples.

- **Classification.** As discussed above, classification is the task of identifying to which of a set of categories new observations belong. For a long time, the most popular approach to solving non-linear classification problems (i.e., the classification of non-separable data) was to apply a multilayer perceptron, i.e., an artificial neural network model that maps a set of input data onto a set of appropriate outputs (Rumelhart *et al.*, 1988). The introduction of SVMs – the most typical kernel based method (Boser *et al.*, 1992), lead to a completely different point of view. In this case, the novel idea was to detect, in the feature space, a discriminating hyperplane that maximize the distance between the nearest points of the two classes (i.e., the maximum margin hyperplane).
- **Regression.** When data are non-linearly related and the task is to fit, as much as possible, the observed examples with a smoothed function, kernel regression can be effectively applied. Similarly to SVM classification, the main mathematical tools of this technique come from mathematical optimization theory.
- **Principal Component Analysis (PCA).** PCA projects the input patterns into a new space spanned by the principal components. Each component is selected to be orthonormal to the others and to capture the maximum variance that is not already accounted for by the previous components.
- Similarly to other kernel algorithms, PCA can be extended to nonlinear settings by replacing PCA in the pattern space by a feature space representation. The final algorithm consists of solving an eigenvector problem for the kernel matrix (Mika *et al.*, 1999).
- **Independent Component Analysis (ICA).** The goal of ICA is to find a linear representation of non-Gaussian data in such a way that the components are statistically independent (or as independent as possible).

This representation can be used to capture the essential structure of the data in different applications, including feature extraction and signal separation.

The kernel ICA (Bach and Jordan, 2002) is based on the minimization of a contrast function, following typical kernel approach ideas. Specifically, a contrast function, in this case, measures the statistical association between components. It can be shown that minimizing these criteria leads to flexible and robust algorithms.

Moreover, a relatively recent research area concerns the study of deep neural networks (Hinton *et al.*, 2006; Deng *et al.*, 2014) and their relationships to kernel approaches (Yger *et al.*, 2011; Cho and Saul, 2009). In this respect, it is important to note that

generalization ability is limited by the choice of a proper kernel function, i.e., the choice of an appropriate kernel has a fundamental effect on the inference performance. For this reason, researchers – in particular from neural network community – attempted to solve this limitation by considering the so called deep kernel strategies.

This paradigm aims at learning useful features by stacking successive layers of transformations. The information represented at each layer is produced by a nonlinear projection of output of the previous layer using kernel method.

In general, researchers have advanced several motivations for these systems, for example, the ability to parametrize a wide number of functions through the combination of simple nonlinear transformations, the expressiveness of distributed hierarchical representations, and the ease of combining supervised and unsupervised methods. Experiments have also shown the benefits of deep learning in several interesting applications (Collobert and Weston, 2008; Bengio *et al.*, 2009).

Conclusion

Kernel methods have not only enriched the machine learning research by offering the opportunity to dealing with different tasks and different input structures, but have also provided new perspectives for solving typical problems with a methodology supported by strong intuition and well founded mathematical theory.

The discussion outlined in this article is intended to provide the fundamental idea of these techniques: whenever a procedure is adapted to use only inner products between input examples, then in that procedure, inner products can be replaced by a kernel function. By exploiting the so-called kernel trick, we have seen that one can straightforwardly perform nonlinear transformations of the original patterns into a (generally) higher dimensional feature space – which is consequently nonlinearly related to the input space. Many algorithms in the scientific literature have been “kernelized” (i.e., adapted) in the manner described above.

Kernel Methods: Support Vector Machines

Italo Zoppis and Giancarlo Mauri, University of Milan-Biocca, Milan, Italy

Riccardo Dondi, University of Bergamo, Bergamo, Italy

Introduction

Among the most mentioned algorithms in the scientific literature of machine learning, Support Vector Machines (SVMs) have played an important role (Vapnik, 1995, 1998) since their introduction in 1992 at the Conference on Computational Learning Theory by Boser *et al.* (1992). They provide a general approach to different inferential tasks such as classification, clustering, and regression, based on a consistent mathematical theory and intuitive functional aspects.

To better understand the formal arguments presented in this article, we will first introduce three main key concepts on which the SVM's functional mechanism is conceptually motivated: i.e., maximum margin hyperplane, the kernel function, and non-linearly separable data. We will mainly refer to typical machine learning procedures, first of all considering the classification problem.

Subsequently, the fundamental mathematical issues for linear and nonlinear classification will be introduced. Notice that, while the mathematical tools of these techniques lie in optimization theory, here we will confine the formal arguments only to the most intuitive topics as well as, to the relationships that express the reasons why the SVMs and the kernel methods have found an effective coexistence.

Finally, considering different contributions in the literature, we will see how binary classification can be extended to clustering, regression and to multi-class classification.

Maximum Margin Hyperplane

Maximum margin hyperplane is one of the key concepts that best explains how SVMs work in practice. To better understand the main idea behind its usage, let us consider the following procedure for separating two kinds of objects (generally called *patterns*).

1. Represent input patterns in a high dimensional space, and
2. draw a (*decision*) linear boundary between them.

This procedure solves one of the most studied task in the machine learning community: the classification problem. The objective of classification is identifying to which of a set of categories new observations belong, on the basis of a sample of data representing observations whose category membership are known (*training set*).

The training set constitutes a collection of labeled examples that might be useful to build the decision boundary, i.e., to fit a prediction model for new unobserved cases. For example, in a typical healthcare classification problem, one might be asked to determine whether new subjects can be discriminated from case patients (diseased patients) or classified as controls (healthy) according to previous sets of sampled attribute values (see, for example, Chinello *et al.*, 2014; Cava *et al.*, 2013a,b when data are combined from different sources of information.).

In general, when the space of the representation (the input space, or as it is sometimes called, *the pattern space*) is $\mathcal{R}^2$, the boundary separates the plane into two half-planes, one that contains positive patterns, and one that contains negative ones. When it is assumed that the input data satisfy the condition of being linearly-separable, it is always possible to find such straight line in $\mathcal{R}^2$. When we have $\mathcal{R}^d$ with $d > 2$, we say that a separating hyperplane exists, and a linear separation boundary can discriminate the two classes of points. After successful training (i.e., identification of the decision boundary), the trained model should correctly predict the output membership class of new patterns, depending on whether new test points fall either within the positive or the negative semi-plane.

There are an infinite number of decision boundaries suitable to discriminate patterns, and many classifiers in literature, following some particular criterion (e.g., gradient descent for back-propagation networks) have achieved accurate performances. As we will see, compared to other methods, SVMs perform this task in a particularly targeted and intuitive manner. The discriminating boundary is given by a hyperplane suitably located to maximize the distance (the margin) that separate it from the closest positive and negative examples (known as support vectors). In this case, the separating hyperplane is called the *maximum margin hyperplane* (Fig. 1).

In order to explain intuitively why this mechanism works, we can consider a case where no preference is given to a particular input distribution, if we place, for example, the boundary too near to the negative points, we would over-predict positive labels (i.e., labeled as $y = +1$). Instead, we will risk for false assignments, on cases labeled as $y = -1$. In this way, a reasonable choice would place the separation boundary as far away as possible from both the closest positive and negative training examples, or in other words, as we will see more formally, right in the middle of these points. More importantly, this insight is supported by statistical learning theory (Vapnik, 1995), that shows that the ability to generalize, in this case, depends on the margin (defined as the distance of the decision hyperplane from the closest data), rather than the dimensionality of the feature space.

Soft Margin and Slack Variables

In practice, it is difficult to find linearly separable data. Noise is a typical characteristic of real-world contexts, which makes it unlikely to detect linear boundaries in classification problems. In such cases, the constraint of maximizing the margin of a linear

Fig. 1 The margin can be defined as the distance between the separating hyperplane and the hyperplanes through the closest points (i.e., support vectors). x_1 and x_2 are examples of support vectors from different classes.

separator can be relaxed. This simple solution is generally known as a *Soft Margin Classifier* (Shawe-Taylor and Cristianini, 2002). This problem motivates the development of more robust solutions that can tolerate noise and, more generally, variability and errors in the training set, without drastically altering the final results.

In order to train a Soft Margin Classifier, an additional set of coefficients is generally introduced that, in turn, allow margin variations for each defined space dimension. These coefficients are known as *slack variables*. Clearly, this increases the complexity of the model as there are more parameters to fit.

Kernel Function

Although the soft margin approach may work for data that are close to being linearly separable, it returns poor results when inputs are strongly affected by errors and variations. In this case, the solution offered by kernels comes into play. This is generally the case for real data sets, where training examples, are generally dispersed and overlapped up to some extent.

It is important to recall that kernel functions work by embedding input patterns into a vector space, where geometric and algebraic techniques can be properly applied to provide linear separation. In particular, by reformulating the learning algorithms in a way that only requires knowledge of the inner product between the input in the embedding space, one can use a kernel function without explicitly performing such embedding. There is no need to know the coordinates of each point in the embedding space, rather it is possible, thanks to the evaluation of the kernel function to directly obtain the inner products between points in such a space. The kernel approach of the SVMs is relatively simple, and can be described as follows.

1. Embed the training patterns into a new (generally, high dimensional) space, and
2. separate, in that space, the two classes of points using a maximum margin hyperplane.

SVM Formulation for Classification Problems

As mentioned above, the intuitive idea that describes how SVMs perform binary classification, is based on the maximum margin hyperplane criterion, i.e., SVM finds the plane that discriminates positive from negative labeled data with the maximum margin. This margin is defined as the distance from the closest input training examples (or support vectors). We now consider two main cases. The first, when data are linearly separable. The second, when they are not.

Separable Data

Let us assume, we are given the following set of examples (i.e., the training set).

$$\mathcal{T} = \{(\mathbf{x}_1, y_1), (\mathbf{x}_2, y_2), \dots, (\mathbf{x}_N, y_N)\} \in \mathcal{X} \times \mathcal{Y} \quad (1)$$

where $\mathbf{x}_i$ is a real vector in $\mathcal{R}^n$ and y_i is either 1 or -1 , representing the class to which point $\mathbf{x}_i$ belongs. Since the objective of SVM is to find a separating hyperplane, in this case, at least one such hyperplane must exist. This hyperplane is generally denoted as

$(\mathbf{w}, b)$, and can be described by the points that satisfy the following general equation.

$$\langle \mathbf{w}, \mathbf{x} \rangle + b = \sum_{i=1}^N w_i x_i + b = 0 \quad (2)$$

Geometrically, $\mathbf{w}$ is a normal vector of the hyperplane that defines the hyperplane orientation, and b is a scalar called the intercept or bias.

Any hyperplane $\pi = (\mathbf{w}, b)$ divides the space $\mathfrak{R}^n$ into two parts, located on opposite sides of the hyperplane, called the positive and negative half-spaces. The positive half-space $(\mathfrak{R}^n)^+_\pi$ is specified by the normal vector of the hyperplane, and for any vector $\mathbf{x} \in (\mathfrak{R}^n)^+_\pi$ we have $\langle \mathbf{w}, \mathbf{x} \rangle + b > 0$, while for any $\mathbf{x} \in (\mathfrak{R}^n)^-_\pi$ we have $\langle \mathbf{w}, \mathbf{x} \rangle + b < 0$.

In other words, for linearly separable data, any hyperplane $(\mathbf{w}, b)$ in $\mathfrak{R}^n$, induces a linear decision boundary able to discriminate the two classes of points $C_1 = \{\mathbf{x} : (\mathbf{x}, \gamma) \in \mathcal{T}, \gamma = +1\}$ and $C_2 = \{\mathbf{x} : (\mathbf{x}, \gamma) \in \mathcal{T}, \gamma = -1\}$ if the following fact holds.

$$\langle \mathbf{w}, \mathbf{x} \rangle + b > 0 \quad \forall \mathbf{x} \in C_1$$

$$\langle \mathbf{w}, \mathbf{x} \rangle + b < 0 \quad \forall \mathbf{x} \in C_2$$

Therefore, we can associate to the separating hyperplane $(\mathbf{w}; b)$ the following (decision) function.

$$h_{\mathbf{w}, b}(\mathbf{x}) = \text{sgn}\{\langle \mathbf{w}, \mathbf{x} \rangle + b\} = \begin{cases} +1 & \text{if } \langle \mathbf{w}, \mathbf{x} \rangle + b > 0 \\ -1 & \text{if } \langle \mathbf{w}, \mathbf{x} \rangle + b < 0 \end{cases} \quad (3)$$

Function in Eq. (3) gives us a rule that correctly classifies all vectors from C_1 and C_2 , using the training examples in $\mathcal{T}$. The SVM training phase therefore has the task to find the weights, $\mathbf{w} = (w_1, w_2, \dots, w_N)$, and the bias, b , of the hyperplane $(\mathbf{w}, b)$.

Functional and Geometric Margin

To provide a formulation for the SVM algorithm, it is instructive to start with a formal definition of the notion of margin. The idea of margin is justified by the need to seek maximum separation between the classes, as described intuitively in the previous paragraph. For this reason, it should be useful to have a confidence measure, on the hyperplane's classification ability, to inform us whether a particular point is properly classified. Moreover, this measure should also quantify the magnitude of the distance between patterns and the separating hyperplane. Clearly, the greater the distance, the greater our confidence in the classification.

Let us assume that $\mathbf{x}_i$ is a vector in $\mathfrak{R}^n$, and $(\mathbf{x}_i, \gamma_i)$ an example in $\mathcal{T}$. We call *functional margin* $\hat{\gamma}_i$ of $\mathbf{x}_i$ with respect to the hyperplane $(\mathbf{w}, b)$ the following quantity.

$$\hat{\gamma}_i = \gamma_i (\langle \mathbf{w}, \mathbf{x}_i \rangle + b) \quad (4)$$

Notice that if $\gamma_i = 1$, then for the functional margin to be large (i.e., for our prediction to be confident and correct), we need $\langle \mathbf{w}, \mathbf{x}_i \rangle + b$ to be a large positive number. Conversely, if $\gamma_i = -1$, then for the functional margin to be large, we need $\langle \mathbf{w}, \mathbf{x}_i \rangle + b$ to be a large negative number. Therefore, if $\gamma_i (\langle \mathbf{w}, \mathbf{x}_i \rangle + b) > 0$, our prediction of the example $(\mathbf{x}_i, \gamma_i)$ is correct. Hence, a large functional margin represents a confident and a correct prediction. However, we have also to consider that by scaling $\mathbf{w}$ and b by any constant factor α (for example, if we replace $\mathbf{w}$ by $3\mathbf{w}$ and b by $3b$), we could make the margin value much larger, but there would be no change in the performance of classifier itself. Indeed, when we try to optimize the expression 4, we can always make the functional margin as big as we wish by simply scaling up $\mathbf{w}$ and b , without really changing anything meaningful in the set of points that satisfy the following equation.

$$\alpha (\langle \mathbf{w}, \mathbf{x} \rangle + b) = 0$$

Thus, we can always obtain an infinite number of equivalent formulations for the same hyperplane. To remove this ambiguity, we consider the following expression.

$$\gamma_i = |\langle \mathbf{w}, \mathbf{x}_i \rangle + b| / \|\mathbf{w}\| \quad (5)$$

Eq. (5) simply normalizes the functional margin by the euclidean norm, $\|\mathbf{w}\|$, of $\mathbf{w}$. Since $\gamma_i \in \{-1, +1\}$, Eq. (5) can also be written (for correctly classified patterns) as follows.

$$\gamma_i = \gamma_i (\langle \mathbf{w}, \mathbf{x}_i \rangle + b) / \|\mathbf{w}\| \quad (6)$$

The quantity γ_i is known as *geometric margin* of $(\mathbf{w}, b)$ with respect to the training example $(\mathbf{x}_i, \gamma_i)$. Note that if $\|\mathbf{w}\| = 1$, then the functional margin equals the geometric margin, thereby relating the two different notions of margin. Also, the geometric margin is invariant to rescaling of the parameters: by replacing $\mathbf{w}$ with $2\mathbf{w}$ and b with $2b$, the geometric margin does not change. Moreover, we can also define the geometric margin of $(\mathbf{w}, b)$ with respect to the training set $\mathcal{T}$ as the smallest of the geometric margins on the individual training examples, i.e.,

$$\gamma = \min_{i=1, \dots, N} \gamma_i \quad (7)$$

A similar definition can also be given for any functional margin $\hat{\gamma}$.

SVM – Primal Optimization Problem

Geometric margin γ provides a natural measure to formulate the maximum margin criterion. This formulation can be described as the following optimization problem.

$$\begin{aligned} \max_{\mathbf{w}, b} \quad & \gamma \\ \text{s.t.} \quad & \gamma_i(\mathbf{w}'\mathbf{x}_i + b) \geq \gamma, \forall i \\ & \|\mathbf{w}\| = 1 \end{aligned} \quad (8)$$

Where, $\mathbf{w}'$ is the transpose of $\mathbf{w}$, which is needed to calculate Eq. (8).

The problem reported in expression 8 maximizes γ , subject to each training example having a functional margin of at least γ . The constraint $\|\mathbf{w}\| = 1$ ensures that the functional margin equals the geometric margin. In this way, we are also guaranteed that all the geometric margins (with reference to all training examples) are at least γ . Thus, solving problem 8 will result in the identification of a hyperplane $(\mathbf{w}, b)$ with the largest possible geometric margin, with respect to the training $\mathcal{T}$. Since the geometric and functional margins are related by $\gamma = \hat{\gamma}/\|\mathbf{w}\|$, we can write the following problem.

$$\begin{aligned} \max_{\mathbf{w}, b} \quad & \hat{\gamma}/\|\mathbf{w}\| \\ \text{s.t.} \quad & \gamma_i(\mathbf{w}'\mathbf{x}_i + b) \geq \hat{\gamma}, \forall i \end{aligned} \quad (9)$$

The objective of Eq. (9) is still non-convex, but considering our earlier discussion on margins, we can arbitrarily scale $\mathbf{w}$ and b without influencing the final computation. This is the key idea we'll apply now.

The scaling constraint can be introduced by requiring that the functional margin of $(\mathbf{w}, b)$, with respect to the training set, must be equal to 1, i.e., $\hat{\gamma} = 1$. Inserting this into Eq. (9), and noting that maximizing $\hat{\gamma}/\|\mathbf{w}\| = 1/\|\mathbf{w}\|$ is the same thing as minimizing $\|\mathbf{w}\|^2$, we have the following formulation.

$$\begin{aligned} \min_{\mathbf{w}, b} \quad & \frac{1}{2} \|\mathbf{w}\|^2 \\ \text{s.t.} \quad & \gamma_i(\mathbf{w}'\mathbf{x}_i + b) \geq 1, \forall i \end{aligned} \quad (10)$$

Eq. (10) is convex with a quadratic objective and linear constraints. Thus, we can finally obtain the solution by applying any quadratic optimization solver (Ding *et al.*, 2004).

SVM – Dual Optimization Problem

The concept of duality plays an important role in the theory of mathematical programming. It turns out that, for many optimization problems, we can easily provide an associated optimization problem, called a dual, whose solution is related to the original (primal) problem solution. Specifically, for a wide range of problems, the primal solutions can be computed from the dual ones.

In case of the maximum margin hyperplane, the dual formulation has two major benefits: its constraints are easier to handle than the constraints of the primal problem, and it is better suited to deal with the kernel function. Moreover, the theory of duality guarantees that the unique solution of the primal problem corresponds to the unique solution of the dual problem. Here, without discussing further mathematical details of the primal-dual theory (the readers interested in the derivation details are encouraged to see, for example, Rockafellar (1982)), we obtain the following dual formulation.

$$\begin{aligned} \max_{\alpha} \quad & \mathcal{W} = \sum_{i=1}^N \alpha_i - \frac{1}{2} \sum_{i,j} \alpha_i \alpha_j \gamma_i \gamma_j \langle \mathbf{x}_i, \mathbf{x}_j \rangle \\ \text{s.t.} \quad & \sum_i \alpha_i \gamma_i = 0 \\ & \alpha_i \geq 0, i = 1, 2, \dots, N \end{aligned} \quad (11)$$

Specifically, in the dual formulation in Eq. (11), we have a maximization problem in which the parameters are the coefficients, α_i , known as *Lagrangian multipliers*, for the training points $i = 1, \dots, N$. Eq. (11) is still a quadratic program and can be solved using any quadratic programming algorithm. Solving this problem for α_i , $i = 1, \dots, N$, i.e., by finding the α_i 's that maximize $\mathcal{W}(\alpha)$, permits (again, using the primal-dual theory) one to find the optimal value for the maximum margin hyperplane, $(\mathbf{w}^*, b^*)$, leading to the following classification function for new test points.

$$h_{\mathbf{w}^*, b^*}(\mathbf{x}) = \text{sgn} \left(\sum_{i=1}^N \alpha_i^* \gamma_i \mathbf{x}_i^T \mathbf{x} + b^* \right) \quad (12)$$

The base mathematical theory (specifically, the Karush-Kuhn-Tucker conditions) provides also useful information about the structure of the solution. In our case, we have the following important facts.

- The points $\mathbf{x}_i$, for which $\alpha_i^* > 0$ contributes to the weight vector (i.e., the location of the large margin hyperplane), and have minimum margin, are called *support vectors*. Importantly, due to this property the number of support vectors is generally very small.
- All the other training examples do not contribute to the weight vector. If we remove all the examples $(\mathbf{x}_i, y_i) \in \mathcal{T}$ for which the α_i^* s are not support vectors, we get the same solution $(\mathbf{w}^*, b^*)$.

The support vectors give, in some sense, a compact representation of the data. SVMs neglect non-informative patterns and considers only those data near to the optimal hyperplane. This compact representation of the solution is useful, especially when large data-sets are considered. Finally, notice that both Eq. (11) and the Eq. (12) exclusively involve inner products on input patterns, thus the dual problem provides not only a different perspective for optimization, but also a way of employing kernel functions, as we will see in the next paragraphs.

Non-Separable Data

Since it is not unusual to find non-separable data, it is necessary to adapt the formulation of Eq. (8). The case we discuss here makes it possible to have violations (i.e., errors) of the discrimination ability of the linear decision boundary. This case is also note as a *soft margin* classifier. For this purpose, when using a linear discriminant, it is possible to provide constraint relaxations, in such a way that errors are allowed, up to some extent. This can be done by introducing *slack variables*, that characterize errors and, at the same time, a control parameter in the objective function to penalize such violations. More specifically, this can be formulated by taking into account, for each example, the following constraints.

$$y_i(\mathbf{w}'\mathbf{x}_i + b) \geq 1 - \xi_i$$

where ξ_i are the slack variables that quantify the amount by which the discriminant function fails to reach the (functional) unit margin. The optimization problem then becomes,

$$\begin{aligned} \min_{\mathbf{w}, b, \xi} \quad & \frac{1}{2} \|\mathbf{w}\|^2 + C \sum_{i=1}^N \xi_i \\ \text{s.t.} \quad & y_i(\mathbf{w}'\mathbf{x}_i - b) \geq 1 - \xi_i, i = 1, \dots, N \\ & \xi_i \geq 0, i = 1, \dots, N \end{aligned} \quad (13)$$

Eq. (13) is still a quadratic program. Generally, C is a positive constant, introduced to control the tradeoff between the penalty and the margin.

Following a similar argument for the separable case, one can obtain the following dual formulation.

$$\begin{aligned} \max_x \quad \mathcal{W} = \quad & \sum_{i=1}^N \alpha_i - \frac{1}{2} \sum_{i,j} \alpha_i \alpha_j y_i y_j \langle \mathbf{x}_i, \mathbf{x}_j \rangle \\ \text{s.t.} \quad & \sum_i \alpha_i y_i = 0 \\ & 0 \leq \alpha_i \leq C, i = 1, \dots, N \end{aligned} \quad (14)$$

This is almost the same optimization problem obtained previously, but with the further constraint on the multipliers, α , which now have an upper bound of C .

Indeed, it is noteworthy that the input data of Eq. (14) depend only on the inner products $\langle \mathbf{x}_i, \mathbf{x}_j \rangle$, thus ensuring the immediate possibility of introducing a kernel function, as we will see in the next paragraph.

Kernels in SVM Algorithms

According to the definition of a kernel, all operations that exclusively involve inner products $\langle \Phi(\mathbf{x}_i), \Phi(\mathbf{x}_j) \rangle$, in some feature space, can be implicitly evaluated in the pattern space by an appropriate kernel function $k(\mathbf{x}_i, \mathbf{x}_j)$. A nonlinear version of an algorithm can be then obtained, by simply replacing the inner products with the kernel functions. This is called the kernel technique (kernel trick).

It should be clear now that the dual formulation is important for this task. In order to see how this is accomplished for the SVM approach, we can simply re-write the dual Problem's objective, Eq. (14), in the feature space, i.e., in terms of $\langle \Phi(\mathbf{x}_i), \Phi(\mathbf{x}_j) \rangle$. In this way, we have the following expression.

$$\max_x \quad \mathcal{W} = \sum_{i=1}^N \alpha_i - \frac{1}{2} \sum_{i,j} \alpha_i \alpha_j y_i y_j \langle \Phi(\mathbf{x}_i), \Phi(\mathbf{x}_j) \rangle$$

Thus, we can obtain the final problem formulation, after the kernel substitution, as reported here.

$$\max_x \quad \mathcal{W} = \sum_{i=1}^N \alpha_i - \frac{1}{2} \sum_{i,j} \alpha_i \alpha_j y_i y_j k(\mathbf{x}_i, \mathbf{x}_j)$$

Similarly, it can be shown that new examples can be classified by applying the following expression.

$$h(\mathbf{x}) = \text{sgnz.drule}; z.\text{drule}; \text{bigg}(\sum_i \alpha_i y_i (\langle \Phi(\mathbf{x}_i), \Phi(\mathbf{x}) \rangle + b) z.\text{drule}; z.\text{drule}; \text{bigg})$$

The new instance $\mathbf{x}$ depends on the data only through inner products in the feature space. Again, the inner product can be replaced with a (nonlinear) kernel function, performing maximum margin classification in the feature space using the kernel from the original pattern space.

Others SVM Extension Algorithms

The previous section has focused on classification problems where classes were labeled within the set $\{-1, +1\}$. Similar arguments can be extended to different typical tasks. Here, we briefly consider the cases of multi-class classification, clustering, and regression.

Multi-Class and One-Versus-All Classifiers

Real observations can belong to more than two groups or classes of objects. In this case, the *multi-class classification* algorithm extends the standard case we have considered so far.

One of the simplest approaches used in the multi-class classification is the so called *one-versus-all approach*, in which the observations belonging to an arbitrary class j have to be discriminated from all other classes, $j = 1, \dots, k$. Here, all the observations from classes other than j are combined to define one common class. The optimal hyperplane separating samples from the class j and the combined class is found using a standard SVM approach, as described above.

Generalizing to multi-class problems is straightforward. Multiple one-versus-all classifiers can be trained, and then the obtained answers can be combined with a general decision function. For example, denoting with $(\mathbf{w}^{(j)}, b^{(j)})$ the optimal hyperplane for class j , and $t^{(j)} = \text{sgn}(\langle \mathbf{w}^{(j)}, \mathbf{x} \rangle + b^{(j)})$, the decision function for j after all the k optimal separating hyperplanes have been found, the final classifier h is given by the following (decision).

$$h(\mathbf{x}) = \text{argmax}_j (t^{(j)}(\mathbf{x})) \quad (15)$$

This approach of assigning class labels using the rule in Eq. (15) is generally called voting. In this case, voting is performed by giving every classifier a vote of size one, and the unknown label is the index of the classifier giving only positive votes. If positive votes are not provided or more than one classifier, t_j , provide positive votes, then no decision about the class label is made.

Different more accurate approaches have been proposed in the literature, for example, binary classifiers can also be represented as a *tree*, such that multi-class classification is obtained by binary classifications at each node of the tree (Platt et al., 1999).

Support Vector Clustering

Differently from classification, clustering is the problem of partitioning the input data into groups in such a way that a particular criterion or relationships between items, belonging to the same group, is satisfied. In this way, the original input patterns are generally organized into a more meaningful form, allowing one to identify homogeneous set of items.

While the literature describes many ways to achieve this goal, Support Vector Clustering (SVC) (Ben-Hur et al., 2001) introduced an interesting and effective technique. First, following the kernel paradigm, inputs are mapped from the original space to a high dimensional feature space using a proper kernel function. Then, in the feature space, the smallest hypersphere enclosing most of the patterns is identified. This sphere, when mapped back to the original space, forms a set of contours that enclose the original samples. It is easy to consider these contours as cluster boundaries. In this way, the points enclosed by each contour are associated by SVC with the same group.

The cluster description algorithm does not differentiate between points that belong to different clusters. At this aim, we can apply a geometric approach that involves the following important observation. Given a pair of patterns belonging to different clusters, each segment that connects them must exit from the sphere in the function space. Such a path contains a point z with $R(z) \geq R$, i.e., its distance from the center of the sphere in the feature space, is greater than the ray of the enclosing sphere. Using this observation, we can define an adjacency matrix, $A_{i,j}$, between pairs of points, $\mathbf{x}_i$ and $\mathbf{x}_j$, whose images lie in or on the sphere in feature space. More formally,

$$A_{i,j} = \begin{cases} 1 & \text{for all } z \text{ on the line segment connecting } \mathbf{x}_i \text{ and } \mathbf{x}_j \\ 0 & \text{otherwise} \end{cases} \quad (16)$$

Clusters can be finally defined as the connected components of the graph induced by A .

Unfortunately, for practical purposes, in order to check whether any pair of inputs is within the same cluster, it is necessary to sample a number of points over the line segment that connects these data in the original pattern space. Hence, the time complexity of the cluster labeling part is generally a critical issue. For example, given M sampled points, on the segment connecting all pairs of input, one has to check their connectivity, based on the decision criterion: $R(z_i) \geq R$, for all $i = 1, \dots, M$ and input pairs $\mathbf{x}_i$ and $\mathbf{x}_j$. To

solve this issue different methodologies have been applied, for example in [Pozzi et al. \(2007\)](#) an appropriate simplification (derived from the approximation of a combinatorial optimization problem) on the adjacency matrix A (in [Eq. \(16\)](#)) is given to avoid useless sampling.

Support Vector Regression

Regression is the process of exploring the relationship between (dependent) variables, Y , and one or more (explanatory) variables, X . This relationship is generally provided by fitting a function, $h(\mathbf{x})$, using a sample of observations from X and Y . The function h then can be used to infer the output $\hat{y}=h(\mathbf{x})$ of new unobserved points. The general approach to this problem can be formulated using a loss function $\mathcal{L}(y, h(\mathbf{x}))$, which describes how the estimated $\hat{y}$ deviate from the true values, y , of the examples $(\mathbf{x}, y)$.

Following the most common approach to SV regression (Vapnik's ε -intensive loss function ([Vapnik, 1995](#))), we have

$$\mathcal{L}(y, h(\mathbf{x})) = \begin{cases} 0 & \text{if } |y - h(\mathbf{x})| \leq \varepsilon \\ |y - h(\mathbf{x})| - \varepsilon & \text{otherwise} \end{cases} \quad (17)$$

where $\varepsilon \geq 0$ is a constant that controls the noise tolerance. Using this loss function, we can view the regression problem as the task of finding a band (or tube), of size of at most ε , around the hypothesis function, h . More formally, let us assume to have the following training data.

$$\mathcal{T} = \{(\mathbf{x}_1, y_1), (\mathbf{x}_2, y_2), \dots, (\mathbf{x}_n, y_n)\} \in \mathcal{X} \times \mathfrak{R},$$

where $\mathcal{X}$ denotes the space of the input patterns. [Eq. \(17\)](#) expresses the fact that, in order to estimate h , we can actually tolerate at most ε deviation from the obtained targets y , for all the training data. In other words, we don't care about errors, as long as they are less than ε , but will consider all deviations larger than this value. Moreover, it is generally required that h should be as flat as possible. If we assume h is a linear function, we have

$$h(\mathbf{x}) = \langle \mathbf{w}, \mathbf{x} \rangle + b \quad (18)$$

where $\mathbf{x} \in \mathcal{X}$ and $b \in \mathfrak{R}$. In this case, flatness means that one seeks small $\mathbf{w}$. One way to ensure this flatness is to minimize the Euclidean norm $\|\mathbf{w}\|^2$. Thus, we can write the following convex optimization problem.

$$\begin{aligned} \min \quad & \frac{1}{2} \|\mathbf{w}\|^2 \\ \text{s.t.} \quad & y_i - (\langle \mathbf{w}, \mathbf{x}_i \rangle + b) \leq \varepsilon, \forall i \\ & (\langle \mathbf{w}, \mathbf{x}_i \rangle + b) - y_i \leq \varepsilon, \forall i. \end{aligned}$$

Also in this case, we can introduce slack variables, ξ_i, ξ_i^* , to provide a soft margin, as described in the previous paragraphs. These slack variables are zero for points inside the band, and progressively increase for points outside the band, according to the loss function ([Fig. 2](#)). Hence we arrive at the following formulation.

$$\begin{aligned} \min \quad & \frac{1}{2} \|\mathbf{w}\|^2 + C \sum_{i=1}^N (\xi_i + \xi_i^*) \\ \text{s.t.} \quad & y_i - (\langle \mathbf{w}, \mathbf{x}_i \rangle + b) \leq \varepsilon + \xi_i, \forall i \\ & (\langle \mathbf{w}, \mathbf{x}_i \rangle + b) - y_i \leq \varepsilon + \xi_i^*, \forall i. \\ & \xi_i, \xi_i^* \geq 0. \end{aligned}$$

Fig. 2 Nonlinear regression function. The variable ξ measures the cost of a training error, corresponding to patterns outside the band.

The constant C determines the trade-off between the flatness of h and the degree to which deviations larger than ε are tolerated. Similarly to the previous formulations, it is possible to show that the dual form can be described in terms of inner products between the input patterns.

Conclusions

Support vector machines have provided a remarkable contribution, not only to the entire scientific community of machine learning, but also to the most diverse scientific and humanistic areas, where statistical inference is currently applied to many important problems. In fact, the exponential growth of SVM's application has shown the effectiveness of this method.

In this article we have discussed the rationale of such algorithms, their intuitive functional aspects, as well as the reasons why the kernel methods and SVMs have found an extremely natural and effective coexistence. Supported by well founded theoretical arguments, SVMs have definitely equaled and exceeded the accuracy level of the state-of-the-art inference models on numerous prediction tasks. Overall, SVMs are intuitive; By identifying a maximal margin hyperplane that separates positive from negative classes, they classify new items depending on the half-space they are located with respect to the separating hyperplane.

Introduction

Kernel methods have received considerable attention in many scientific communities, mainly due to their capability of working with linear inference models, allowing at the same time to identify nonlinear relationships among input patterns (Smola and Schölkopf, 1998; Shawe-Taylor and Cristianini, 2004; Schölkopf and Burges, 1999). Moreover, the possibility offered by these techniques to work homogeneously with structured data has allowed to cope with different problems, even introducing within the inference process specific domain-knowledge.

The discovery of nonlinear relationships between input patterns and the ability to work with heterogeneous data have always been two important and desirable features to be found in machine learning. At this regard, it is necessary to emphasize that kernel methods not only provided these possibilities in a completely natural way, but they were largely founded on a strong and intuitive mathematics.

For a long time, the most popular approach to solve nonlinear problems was to apply *multi-layer perceptron*: a model, able to approximate any function (Hornik et al., 1989), that can be trained efficiently by using the back-propagation algorithm. The approach followed by the kernel methods is fundamentally different. The strategy is to design procedures, in the feature space, by addressing observations only through inner product operations. Such algorithms are said to employ a kernel, since the pairwise inner products can be computed directly from the original items, using only the so called *kernel function*. In other terms, whether an algorithm expressing operations which exclusively involve inner products in some feature space, can be implicitly done in the input space by using an appropriate kernel function. A nonlinear version of the considered algorithm can be readily obtained by simply replacing the inner products with the kernel function (this is generally referred as *kernel trick*). In this situation, it is not necessary to know the input transformation, instead the kernel trick is enough to ensure the existence of such transformation between the input patterns and the feature space.

In this article, we will show how to implement this technique for simple tasks. Moreover, successful applications in machine learning literature, bioinformatics and pattern recognition will be briefly described.

Implementation

Many machine learning algorithms are generally applied on input which are points in a vector space $\mathfrak{R}^n$. When these algorithms can be expressed in terms of inner products between pairs of input patterns, then they can “implicitly” provide input transformations, generally non-linearly related to the input space. As a consequence, linear algorithms can be easily transformed, into nonlinear algorithms, that in turn, can explore complex relationships between input observations. This operational mode is the fundamental feature of kernel methods.

More technically, such algorithms are said to employ kernel functions, since the pairwise inner products $\langle \Phi(x_i), \Phi(x_j) \rangle_{\mathcal{H}}$ between input $\Phi(x_i)$, $\Phi(x_j)$, in the feature space $\mathcal{H}$, can be computed efficiently, directly from the original data items using an appropriate kernel function $k(x_i, x_j)$. In other terms, this function is able to represent, in the original space, the inner product in $\mathcal{H}$. This is formally stated as

$$k(x_i, x_j) = \langle \Phi(x_i), \Phi(x_j) \rangle_{\mathcal{H}} \quad (1)$$

In this way, a nonlinear version of a given learning algorithm can be obtained by simply replacing the inner products with kernels. We will see now some examples of how this technique can be implemented to provide interesting properties of the input patterns, in the function space, and to solve both classification and regression problems.

Distances in Feature Space

Distances and dissimilarities have been important issues in machine learning and pattern recognition for many years, leading to many different known algorithms and important questions e.g., Pekalska and Duin (2005), Ramakrishnan et al. (2010), Cava et al. (2013), (2014). By applying the kernel trick, it is not difficult, to obtain distances between pair of points in the feature space. For this task, we denote with $\mathcal{H}$ the inner product space, where the features are represented through the mapping $\Phi: \mathcal{X} \rightarrow \mathcal{H}$. It is simple to define a distance $d(x_1, x_2)$ between points in $\mathcal{X}$, as the feature distance between input (images) in $\mathcal{H}$. This can be formulated as follows

$$d(x_1, x_2) = \|\Phi(x_1) - \Phi(x_2)\|_{\mathcal{H}}^2 \quad (2)$$

While it seems necessary to explicitly know the images $\Phi(x_1)$ and $\Phi(x_2)$, before providing the distance d , we can evaluate $d(x_1, x_2)$ by applying the kernel substitution. Hence we have,

$$\begin{aligned} \|\Phi(x_1) - \Phi(x_2)\|_{\mathcal{H}}^2 &= \langle \Phi(x_1) - \Phi(x_2), \Phi(x_1) - \Phi(x_2) \rangle \\ &= \langle \Phi(x_1), \Phi(x_1) \rangle - 2\langle \Phi(x_1), \Phi(x_2) \rangle + \langle \Phi(x_2), \Phi(x_2) \rangle \end{aligned}$$

Using the kernel trick, we have the following expression

$$\|\Phi(x_1) - \Phi(x_2)\|_{\mathcal{H}}^2 = k(x_1, x_1) - 2k(x_1, x_2) + k(x_2, x_2) \quad (3)$$

Thus, as expressed by Eq. (3), the distance in the feature space has been obtained assessing pairs of input in the pattern space through the kernel function.

Norm and Distance from the Center of Mass

As a more general example, we consider now the mean π_S (the center of mass) of a set of input patterns $S = \{x_1, x_2, \dots, x_N\}$. Suppose we want to evaluate π_S in the feature space. First of all, we can write the vector π_S as follows

$$\pi_S = \frac{1}{N} \sum_{i=1}^N \Phi(x_i) \quad (4)$$

Despite the apparent inaccessibility of all points $\Phi(x_i)$, and consequently of the mean π_S , we can easily compute $\|\pi_S\|$, by evaluating the kernel function over the input patterns. Indeed, let us consider the following expressions

$$\begin{aligned} \|\pi_S\|^2 &= \langle \pi_S, \pi_S \rangle \\ &= \left\langle \frac{1}{N} \sum_{i=1}^N \Phi(x_i), \frac{1}{N} \sum_{j=1}^N \Phi(x_j) \right\rangle \\ &= \frac{1}{N^2} \sum_{i,j=1}^N \langle \Phi(x_i), \Phi(x_j) \rangle \\ &= \frac{1}{N^2} \sum_{i,j=1}^N k(x_i, x_j) \end{aligned} \quad (5)$$

Notice that, from Eq. (5), the square of $\|\pi_S\|$ is equal to the average of the entries in the kernel matrix G , being defined as follows

$$G_{i,j} = \langle \Phi(x_i), \Phi(x_j) \rangle_{\mathcal{H}} = k(x_i, x_j) \quad (6)$$

Similarly, we can compute the distance of the image of a given point x from the center of mass π_S . In this case, we obtain the following result

$$\begin{aligned} \|\Phi(x) - \pi_S\|^2 &= \langle \Phi(x), \Phi(x) \rangle + \langle \pi_S, \pi_S \rangle - 2\langle \Phi(x), \pi_S \rangle \\ &= k(x, x) + \frac{1}{N^2} \sum_{i,j=1}^N k(x_i, x_j) - \frac{2}{N} \sum_{i=1}^N k(x, x_i) \end{aligned}$$

Binary Classification Problems

Let us consider now a more complete case: the *Binary Classification* problem. Classification is a typical problem in machine learning. Given a training set of examples $\mathcal{T}$, it is asked to construct a specific inference model $\mathcal{M}$, using elements from $\mathcal{T}$. The target is to find the membership class of new items, which have not been used for the model construction. In other words, since any model has generally some free parameters, we can use elements from $\mathcal{T}$ – following particular mathematical techniques, to estimate such values. In binary classification, we assume that the label space $\mathcal{Y}$ contains only the two elements, $+1$ and -1 , while the training set consists of labeled examples of the two classes. When new items are given, the model should be able to answer, which of the two classes a new item belongs.

For classification, we will apply a simple argumentation to associate the class membership for new items. The class (label) will be given, taking into consideration the distance from the center of mass, as discussed in the previous section, i.e., we will assign a new point to the class whose distance is closest. More formally, let $\mathcal{T}$ be an arbitrary training set defined as follows

$$\mathcal{T} = \{(\mathbf{x}_1, y_1), (\mathbf{x}_2, y_2), \dots, (\mathbf{x}_n, y_n)\} \in \mathcal{X} \times \mathcal{Y} \quad (7)$$

Let us assume to work directly in the feature space $\mathcal{H}$, and also assume that our pattern space of reference is $\mathfrak{R}^n$. The sentence, “working in the feature space” exactly means that we will refer to $\Phi(\mathbf{x}) \in \mathcal{H}$, instead of $\mathbf{x} \in \mathfrak{R}^n$, even if one cannot explicitly perceive its components. The reference to $\Phi(\mathbf{x})$ is simply done in order to apply the algorithmic ideas over the new space of representation, in our case, the classification algorithm. As the main intuition, on which our classification is based, is to assign, unseen patterns to classes with closer distance, we will apply this rule in the feature space $\mathcal{H}$. In this way, we first compute the distance of the observed examples from the center of mass — for each membership class, then assign a new point to the class whose distance is closest.

Let S_+ and S_- be the set of positive and negative examples from the training $\mathcal{T}$. Moreover, let $d_+(\mathbf{x}) = \|\Phi(\mathbf{x}) - \Phi_{S_+}\|$ be the distance, in the feature space, of a test point $\mathbf{x}$ from the center of mass Φ_{S_+} of S_+ , and $d_-(\mathbf{x}) = \|\Phi(\mathbf{x}) - \Phi_{S_-}\|$ be the distance of a point $\mathbf{x}$ from the center of mass Φ_{S_-} of S_- . The simple rule we apply here classifies a new item, following the decision function defined as

$$h(\mathbf{x}) = \begin{cases} 1 & \text{if } d_-(\mathbf{x}) > d_+(\mathbf{x}) \\ -1 & \text{otherwise} \end{cases} \quad (8)$$

By expressing $h(\mathbf{x})$ in terms of the sign function, we can obtain the following,

$$\begin{aligned} h(\mathbf{x}) &= \text{sgn}(\|\Phi(\mathbf{x}) - \Phi_{S_-}\|^2 - \|\Phi(\mathbf{x}) - \Phi_{S_+}\|^2) \\ &= \text{sgn}(-k(\mathbf{x}, \mathbf{x}) - \frac{1}{m_+^2} \sum_{i,j=1}^{m_+} k(\mathbf{x}_i, \mathbf{x}_j) + \frac{2}{m_+} \sum_{i=1}^{m_+} k(\mathbf{x}, \mathbf{x}_i) \\ &\quad + k(\mathbf{x}, \mathbf{x}) + \frac{1}{m_-^2} \sum_{i,j=m_++1}^{m_++m_-} k(\mathbf{x}_i, \mathbf{x}_j) - \frac{2}{m_-} \sum_{i=m_++1}^{m_++m_-} k(\mathbf{x}, \mathbf{x}_i)) \\ &= \text{sgn}(\frac{1}{m_+} \sum_{i=1}^{m_+} k(\mathbf{x}, \mathbf{x}_i) - \frac{1}{m_-} \sum_{i=m_++1}^{m_++m_-} k(\mathbf{x}, \mathbf{x}_i) - b) \end{aligned} \quad (9)$$

where we have assumed to assign indexes ranging from 1 to m_+ to positive examples and indexes from $m_+ + 1$ to $m = m_+ + m_-$ to negative examples. Moreover, we denoted with b a constant being half of the difference between the average entry of the positive examples kernel matrix and the average entry of the negative examples kernel matrix. Finally notice that in Eq. (9), we applied the kernel trick to assess input data only through the kernel function.

Kernel Regression

Let us consider now the problem of finding a real-valued linear function

$$h(\mathbf{x}) = \langle \mathbf{w}, \mathbf{x} \rangle = \mathbf{w}'\mathbf{x} \quad (10)$$

that fits as better as possible a given set of points in $X \subseteq \mathcal{R}^n$. The points $\mathbf{x}_i \in X$ are generally provided by the set of observed data

$$\mathcal{T} = \{(\mathbf{x}_1, y_1), (\mathbf{x}_2, y_2), \dots, (\mathbf{x}_N, y_N)\} \quad (11)$$

where the corresponding labels y_i are elements of a set $Y \subseteq \mathcal{R}$. This is a typical regression problem, where it is asked to explore relationships between a dependent variable Y and one (or more) explanatory variable X . The function $h(\mathbf{x})$ in Eq. (10) represents one of the simplest relationships that can be found between X and Y . It expresses a linear function of the input patterns, that match the associated target values y_i . Using this function one can easily define a new pattern function f which, in turn, should assume ideally a value equal to 0. In this way, we can define f as follows

$$f((\mathbf{x}, y)) = |y - h(\mathbf{x})| \quad (12)$$

In general Eq. (12) evaluates an error $|\xi| = f((\mathbf{x}, y)) = |y - h(\mathbf{x})|$ of the linear function h on the particular training example in $(\mathbf{x}, y) \in \mathcal{T}$. Thus the problem can be formulated as the one of finding a function f for which all training errors are as small as possible. The standard classical approach is to use the sum of the squares of errors as measure of the discrepancy between the training data and the particular chosen function. In other terms, we could also say that, we consider here the problem of seeking the parameters $\mathbf{w}$ for which the following loss function is minimized

$$\mathcal{L}(h, \mathcal{T}) = \mathcal{L}(\mathbf{w}, \mathcal{T}) = \sum_{i=1}^N (y_i - h(\mathbf{x}_i))^2 = \sum_{i=1}^N \xi_i^2 = \sum_{i=1}^N \mathcal{L}((\mathbf{x}_i, y_i), h)$$

where we have used the same notation $\mathcal{L}((\mathbf{x}_i, y_i), h) = \xi_i^2$ to represent the squared error of h for the example $(\mathbf{x}_i, y_i)$ and $\mathcal{L}(h, \mathcal{T})$ to denote the collective loss on the training set $\mathcal{T}$. This problem, well-known as least squares approximation, is widely applied in many different discipline. Using the notation above, the vector of output discrepancies can be written as $\xi = \mathbf{y} - \mathbf{X}\mathbf{w}$. Hence, we can also write the loss function as follows

$$L(\mathbf{w}, \mathcal{T}) = \|\xi\|_2^2 = (\mathbf{y} - \mathbf{X}\mathbf{w})'(\mathbf{y} - \mathbf{X}\mathbf{w})$$

The optimal $\mathbf{w}$ can be found by differentiating the loss function with respect to $\mathbf{w}$ and setting them equal to zero (vector), i.e.

$$\frac{\partial L(\mathbf{w}, \mathcal{T})}{\partial \mathbf{w}} = -2\mathbf{X}'\mathbf{y} + 2\mathbf{X}'\mathbf{X}\mathbf{w} = 0 \quad (13)$$

In this way, we get the following equation

$$\mathbf{X}'\mathbf{X}\mathbf{w} = \mathbf{X}'\mathbf{y} \quad (14)$$

If the inverse of $\mathbf{X}'\mathbf{X}$ exists, then we can write the solution of the least squares problem as follows

$$\mathbf{w} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y} \quad (15)$$

As usually, the inferred output on a new input pattern can be obtained applying the prediction function $h(\mathbf{x}) = \langle \mathbf{w}, \mathbf{x} \rangle$. Moreover, notice that if the inverse of $\mathbf{X}'\mathbf{X}$ exists, we can express $\mathbf{w}$ in the following way

$$\mathbf{w} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y} = \mathbf{X}'\mathbf{X}(\mathbf{X}'\mathbf{X})^{-2}\mathbf{X}'\mathbf{y} = \mathbf{X}'\boldsymbol{\alpha} \quad (16)$$

obtaining a linear combination of the training points, as follows

$$\mathbf{w} = \sum_{i=1}^N \alpha_i \mathbf{x}_i \quad (17)$$

Sometime, we can improve the generalization of the algorithm by adding a “penalty” term. In this case, we have the so called *Ridge Regression* that corresponds to solving the following optimization problem

$$\min_{\mathbf{w}} \mathcal{L}_{\lambda}(\mathbf{w}, T) = \min_{\mathbf{w}} (\lambda \|\mathbf{w}\|^2 + \sum_{i=1}^N (y_i - h(\mathbf{x}_i))^2) \quad (18)$$

where $\lambda > 0$ controls the “trade-off between norm and loss.

Similarly to the previous case, by taking the derivative of the loss function with respect to the parameters (13), we get the following equation

$$\mathbf{X}'\mathbf{X}\mathbf{w} + \lambda\mathbf{w} = (\mathbf{X}'\mathbf{X} + \lambda I_N)\mathbf{w} = \mathbf{X}'\mathbf{y} \quad (19)$$

where I_N is a $N \times N$ identity matrix. In this case, the matrix $(\mathbf{X}'\mathbf{X} + \lambda I_N)$ is always invertible for $\lambda > 0$. Therefore, we have the solution

$$\mathbf{w} = (\mathbf{X}'\mathbf{X} + \lambda I_N)^{-1}\mathbf{X}'\mathbf{y} \quad (20)$$

In order to solve this equation for $\mathbf{w}$ we have to solve a system of linear equations with N unknowns variables and N equations. We therefore obtain the final decision function expressed as follows

$$h(\mathbf{x}) = \langle \mathbf{w}, \mathbf{x} \rangle = \mathbf{y}'\mathbf{X}(\mathbf{X}'\mathbf{X} + \lambda I_N)^{-1}\mathbf{x} \quad (21)$$

Equivalently, we can rewrite Eq. (19) in terms of $\mathbf{w}$. Thus we obtain

$$\mathbf{w} = \lambda^{-1}\mathbf{X}'(\mathbf{y} - \mathbf{X}\mathbf{w}) = \mathbf{X}'\boldsymbol{\alpha} \quad (22)$$

Again, $\mathbf{w}$ can be written as a linear combination of the training data

$$\mathbf{w} = \sum_{i=1}^N \alpha_i \mathbf{x}_i \quad (23)$$

with $\boldsymbol{\alpha} = \lambda^{-1}(\mathbf{y} - \mathbf{X}\mathbf{w})$. Hence, we have

$$\begin{aligned} \boldsymbol{\alpha} &= \lambda^{-1}(\mathbf{y} - \mathbf{X}\mathbf{w}) \\ &\Rightarrow \lambda\boldsymbol{\alpha} = (\mathbf{y} - \mathbf{X}\mathbf{X}'\boldsymbol{\alpha}) \\ &\Rightarrow (\mathbf{X}\mathbf{X}' + \lambda I_N)\boldsymbol{\alpha} = \mathbf{y} \\ &\Rightarrow \boldsymbol{\alpha} = (\mathbf{G} + \lambda I_N)^{-1}\mathbf{y} \end{aligned} \quad (24)$$

where $\mathbf{G} = \mathbf{X}\mathbf{X}'$, or equivalently $G_{ij} = \langle \mathbf{x}_i, \mathbf{x}_j \rangle$. Also in this case we can write the predicted output of a new points, obtaining the following result

$$h(\mathbf{x}) = \langle \mathbf{w}, \mathbf{x} \rangle = \langle \sum_{i=1}^N \alpha_i \mathbf{x}_i, \mathbf{x} \rangle = \sum_{i=1}^N \alpha_i \langle \mathbf{x}_i, \mathbf{x} \rangle \quad (25)$$

Notice that, we described two different methods for solving the Ridge regression optimization problem. In the first Eq. (20) the weight vector is computed explicitly (primal solution), while in the second case, reported in Eq. (24), we obtained the solution as a linear combination of the training examples (dual solution), in this last case, the parameters α are known as dual variables.

Finally, we observe an important fact. In the dual solution, the information provided by the training examples is given through the inner products between pairs of training points in the (Gram) matrix $\mathbf{G} = \mathbf{X}\mathbf{X}'$. Similarly, the information about a novel example $\mathbf{x}$ used by the predictive function is again provided as inner products between training points and the new example $\mathbf{x}$. Therefore, like the other examples reported previously, also in the case, the algorithm can be written in a form that only requires inner products between observations.

Kernels and Applications

The most typical and probably mentioned kernel-based algorithm is known as *Support Vector Machine* (Vapnik, 1995, 1998; Boser *et al.*, 1992). Many others algorithmic implementations have been developed and extended within the machine learning community since the introduction of kernel methods. Just to name a few, it is worthwhile to refer to the Kernel Fisher Discriminant Analysis, Kernel Principal Component Analysis and Kernel Independent Component Analysis. Such algorithms have been “kernelized”, in the sense that, starting from the original formulation, they have been adapted (as described above), to assess input

patterns only through inner product operations, in the feature space. This paradigm has been successfully applied to different application areas, providing accurate performances and relative robust results.

The exponential growth of the different applications and the many extensions of these techniques do not obviously allow to draw a full extensive characterization of the current literature on kernels. In this article, we focus on two very important domains: bioinformatics and pattern recognition.

Kernel Methods in Bioinformatics

The huge volume of data produced by biotechnologies (e.g., microarray) has required new methods for extracting and analyzing meaningful information. A multitude of works using the kernel approach emerged, especially for tasks concerning DNA/RNA sequences (Hua and Sun, 2001; Sonnenburg *et al.*, 2002, 2005, 2006; Sakakibara *et al.*, 2007; Sato *et al.*, 2008) and proteins (Tsuda *et al.*, 2002; Tsuda and Noble, 2004a; Ben-Hur and Brutlag, 2003; Liao and Noble, 2003).

The main reason of success of the kernel paradigm in this context is certainly due to both the ability of working homogeneously with many different structures and to the effectiveness with which non-linearity can be introduced into linear algorithms. For example, considering DNA-sequences, the problem is to deal with a variable length which make it hard to represent them e.g., as vectors. Since any valid kernel give rise to a positive semi-definite matrix, the representation of data with that matrix (being independent of the nature or the structure of the data to be analyzed) makes kernels a potential ideal technique for (heterogeneous) data integration and representation. Such issues are investigated e.g., in Daemen *et al.* (2007) where efficient integration of clinical and microarray data are focused.

Among the others omics science, Genomics and Proteomics are currently two successful applications where the requirements of homogeneous representation and nonlinear relationships identification are important to accomplish tasks such as classification, clustering and feature selection. In a sense, these tasks formalize and unify many targets problems of both these omics disciplines.

For example, in genomics, the *gene finding* problem is definitely one of the issues that has been more focused in literature. In particular, gene selection from microarray data is usually formalized as a feature selection task, where the relevant features (i.e., relevant for an accurate prediction) are extremely important for understanding the underlying disease or to get deeper knowledge of the underlying biological process. In this case, the knowledge discovery process, tries either to recursively eliminate irrelevant features or iteratively add most informative ones (Guyon *et al.*, 2008; Gratkowski *et al.*, 2009; Weston *et al.*, 2000).

While the literature on feature selection is older and goes behind the field of the kernel paradigm, several interesting development with kernels have been proposed, explicitly motivated by the problem of gene finding. For example in Su *et al.* (2003), it is proposed to evaluate the predictive power of each single gene for a given classification task by the value of the functional minimized by a SVM model, trained to classify samples from the expression of only the single gene of interest. This is the typical criterion that can be used to rank genes and then select only those with important predictive power. This procedure belongs to the so-called filter approach relevant to the feature selection problem. In this specific case, some score criterion (e.g., obtained using the SVM performances) measures the relevance of each feature, and only higher score features, according to this criterion, are kept.

A second general strategy, for feature selection, is the wrapper approach, where selection procedures alternate with the classifier's training phase. The widely used recursive feature elimination (RFE) procedure of Guyon *et al.* (2002), which iteratively selects smaller sets of genes and trains SVMs, follows this strategy. Starting from the full set of genes, a SVM is trained and the genes with smallest weight values are eliminated. The procedure is then repeated iteratively, using the current set of remaining genes. This process stops when either a specific criterion or a given number of genes is reached.

A third strategy for marker (i.e., gene) selection with the feature selection problem, is known as the embedded approach. In this case, the two phases i.e., learning of a classifier and the selection of features, are combined in a single step. Many kernel methods following this strategy have been implemented, for example in Krishnapuram *et al.* (2004) where, roughly speaking, a variant of SVM with a Bayesian formulation is proposed.

Kernel methods have been successfully applied also to splice site recognition. In this case, the prediction task is to discriminate between sequences that do contain a true splice site versus sequences with a decoy splice site (Sonnenburg *et al.*, 2002). Generally for these problem, particular kernels are employed (e.g., the so-called weighted degree kernel).

Structuring genes in groups (Eisen *et al.*, 1998; Antoniotti *et al.*, 2010; Zoppis *et al.*, 2007) is another important task which is generally formulated as a clustering problem. This task is possibly useful to gain insight into biological and regulatory processes. In Pozzi *et al.* (2007) an application of SVMs to cluster homogeneous features, such as pairs of gene-to-gene interactions is proposed. Specifically, a Support Vector Clustering (SVC) is applied (i.e. a novelty detection algorithm), to provide groups of similarly interacting pairs of genes with respect to some measure (i.e. kernel function) of their activation/inhibition relationships.

Kernel approach in proteomics mainly involved protein function prediction from data sources other than sequence or structure. Some representative studies in this direction can be found in Vert (2002), where a kernel on trees is introduced for function prediction from phylogenetic profiles of proteins. Tsuda and Noble (2004b), reported an inference task to predict the function of unannotated proteins in protein interaction or metabolomic networks. Successful application of SVMs in proteomics also include protein homology detection to determine the structural and functional properties of new protein sequences (Jaakkola *et al.*, 2000). Determination of these properties is achieved by relating new sequences to proteins with known structural features.

Finally, mass spectrometry and peptide identification represent a promising area of research in clinical analysis. They are primarily concerned with measuring the relative intensity (i.e., signals) of many protein/peptide molecules associated with their mass-to-charge ratios. These measurements provide a huge amount of information which requires adequate tools to be

interpreted. In Galli *et al.* (2016) is reported an accurate classification of thyroid bioptic specimens that can be obtained through the application of Support Vector Machines on MALDI-MSI data, together with a particular “wrapper” feature selection algorithm.

Kernel Methods and Pattern Recognition

Pattern Recognition is a mature and fast developing field, which forms the core of many other disciplines such as computer vision, image processing, clinical diagnostics, person identification, text and document analysis. It is closely related to machine learning, and also finds applications in fast emerging areas such as biometrics, bioinformatics, multimedia data analysis and most recently data science.

Within this context, object recognition (and detection) plays a key role in both computer vision and robotics. The task is difficult partly because images are in high-dimensional space and can change with viewpoint, while the objects themselves may be deformable, leading to large variation. The core of building object recognition systems is to extract meaningful representations (features) from high dimensional patterns such as images, videos, or even 3D clouds of points. For examples, moving people or traffic situation e.g., for surveillance or traffic control (Gao *et al.*, 2001). Here the tasks provided by kernel approaches are truly vast. Significant examples can be found in Nakajima *et al.* (2000), where people recognition and pose estimation were implemented as a multi-class classification problem. Many attention has been focused even with detailed situation and difficulties deriving e.g. from noise and occlusion (Pittore *et al.*, 1999).

Many other tasks and object recognition system have been implemented, just to cite a few in Li *et al.* (2000b) is provided a radar target recognition and in Pontil and Verri (1998) Roobaert and Van Hulle (1999) a more general SVM base 3D object recognition system are detailed.

A special topic of pattern recognition is the face recognition. This is also one of the most popular problem in biometrics, and it is of fundamental importance in the construction of security, control and verification systems. The main difficulties arising with these applications, are given by the needs of distinguishing different people who have roughly same facial features. Moreover complications arise due to variations in pose, illumination and facial expression (Wang *et al.*, 2002). Kernels and in particular SVMs have been widely applied in this context since the '90 s (Osuna *et al.*, 1997), collecting many successes both in the specific topics of face detection (Li *et al.*, 2000a; Ai *et al.*, 2001; Ng and Gong, 1999, 2002; Huang *et al.*, 1998) and face authentications (Tefas *et al.*, 2001; Jonsson *et al.*, 2002). While traditionally, face representation in the conventional Eigenface and Fisherface approaches is based on second order statistics of the image data-set, i.e., covariance matrix, and does not use high order statistical properties, much of the important information may be contained in these high order statistical relationships among image's pixels. Using the kernel tricks conventional methods have been extend to feature spaces, where it is possible to extract nonlinear features among more pixels. From these relevant works new specific kernel functions and concepts have become fundamental within the scientific community, i.e., Kernel Eigenface and Kernel Fisher face methods (Yang, 2002). Also in these cases, kernel approaches have shown to be effective and powerful for the development of face recognition platforms.

Conclusions

In this article, we have described how the kernel approach can be easily implemented and applied to simple machine learning problems. We have also discussed how this paradigm has offered new opportunities to the learning machine community. Kernel methods do not only provide two major needs driven by the Information and Communication Technologies i.e., the ability of working homogeneously with different structures and the effectively to introduce non-linearity within prediction models, but they have also given a new important capability: the one of transforming old procedures in new powerful methods for extracting and inferring meaningful information. In fact, many inference algorithms can be designed in such a way to access training data only through inner product operations between pair of input patterns. Such algorithms are said to employ kernels (or kernel function), since the pairwise inner products can be even computed efficiently directly from the original data items, using the kernel function. In this way, we could definitely say that, whether an old or a new methods expressing operations which exclusively involve inner products (in the feature space) can be implicitly done in the input space by an appropriate kernel. This is the way to design a kernel algorithm.

The exponential growth of different applications in many disciplines has shown the effectiveness of this paradigm. Here we focused on two examples of such disciplines: bioinformatics and patter recognition. Many other significant question and interesting challenges are emerging nowadays in the scientific community, mainly due to support limitations of the kernel approach. Just to cite a few of these challenges, the relationship between kernel methods (as well as the whole context of machine learning) and the new emerging learning paradigms on deep architectures and cloud technologies. In the first case (Hinton *et al.*, 2006; Deng *et al.*, 2014), researchers, in particular from neural network community, have advanced several reasons to design the so called *deep learning strategies*. Such paradigm aims at learning useful features by stacking successive layers of transformations. Each layer is issued from a nonlinear projection of output of the previous layer using kernel method. This approach should benefit the expressiveness of distributed hierarchical representation, and the ease of combining supervised and unsupervised methods. Experiments have shown promising results of this methodology in several cases (Collobert and Weston, 2008; Bengio *et al.*, 2009).

In the second case, distributed machine learning has become a fundamental requirement in all big data context. Most of machine learning algorithms have problems with computational complexity of training phase with large scale learning datasets.

Applications of classification algorithms for large volume data-set are computationally expensive to process. The computation time and storage space of kernel algorithms are mainly determined by large scale kernel matrix, which must transmit all the information contained within the pairwise similarity scores evaluated using the applied kernel. In this way, kernel is both the core and crucial information bottleneck of the kernel approach. Different solutions to overcome very large scale classification problems have been provided, for example using distributed SVMs by filtering out non-support vectors elements to optimize the final maximum margin hyperplane over the combined data sets (Graf *et al.*, 2004), or by exchanging in different way the support vectors among the system units (Ruping, 2001; Syed *et al.*, 1999; Lu *et al.*, 2008).

Multiple Learners Combination: Introduction

Chiara Zucco, University "Magna Graecia" of Catanzaro, Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

With the term ensemble we usually refer to a group working for an overall result. Therefore, generally speaking, the idea behind the ensemble learning methods is to combine multiple learners in a suitable way that can improve the accuracy of a decision-making processes.

The idea underlying this methodology has many similarities with what happens in everyday life. Let's think, for example, to democratic electoral systems or medical teams formed by specialists from various fields, or to the requests for an external expertise or to a decision committee (Polikar, 2012).

There are innumerable cases where more opinions are heard to make a better decision and that decision is then made by taking into account and combining the opinions of those experts where, in general, with the term expert we mean a decision-maker who has a lot of knowledge or ability in a certain area. From a computational point of view, an accepted definition of expert can be a model induced by an algorithm that has a good number of past positive records in that particular area, at least more than the random guessing model. In particular, the term "weak" expert/learner/classifier is usually referred to learners having an accuracy that is slightly better than the random guessing algorithm, while a "strong" expert/learner/classifier has a high number of past positive records, so high accuracy.

In real life, if there was an expert of every area of knowledge, or "oracle", responding to any question in a correct way, we did not need to involve more experts, but it doesn't exist. Similarly, there is no single algorithm that induces the most accurate learning model in any domain or, in other words, there are no models that do not have negative records at least in one domain. This is basically expressed in a theorem, known as *No free lunch theorems for optimization* that, in some way, constitute the rationale behind the ensemble methods (Wolpert and Macready, 1997; Wolpert, 2012; Ho and Pepyne, 2002). Instead of looking for the learning model that is the most accurate for that problem, the ensemble learning approach is to combine weak (or base) learner to increase the accuracy of the combined model by compensating for the weaknesses of one learner by the strengths of the others.

One of the theoretical foundations underlying the combined methods, can be found in a result belonging to the political science field, known as the Condorcet's jury Theorem and dating back to 1785 (De Condorcet *et al.*, 2014).

The first approaches to ensemble approaches within the ML date back to the 1960s, in particular one of the first that presented an idealized architectures in which multiple models were built and their outputs were combined with a "demon decision", is the pandemonium paradigm presented by Selfridge (1958).

However, the major contributions regarding both the construction of ensemble models and the methodologies to combine multiple learners, arose in the '90s.

In particular, in 1990 Schapire presented boosting (Schapire, 1990) and in 1996 AdaBoost (Freund *et al.*, 1996) in 1992 Wolpert introduced the stacked generalization scheme, later called stacking (Wolpert, 1992). In Breiman (1996) introduced for the first time another lucky ensemble learning techniques known as Bagging, and in 2000 its most known variant, i.e., Random forest (Breiman, 2001).

The ensemble methods have gained a lot of popularity in the last twenty years because the results have shown both theoretically and practically that combining more weak learners over-emphasize the patterns induced by a single algorithm (also known as base or weak learners) (Polikar, 2012). Intuitively, however, it is evident that combining multiple models has the price of greater computational complexity. For example, if we think of a classification problem, it's easy to understand that training and testing of multiple algorithms requires greater spending on time and space than training and testing of just one algorithm. So it makes sense to wonder what hypotheses should be required for performance gains to be significant compared with the increase in complexity (Alpaydin, 2014).

In this article we will try to answer essentially two questions:

- How to choose the learner base so that the resulting model achieves better overall performance;
- How to combine the outputs of individual learners.

In particular, the article is organized as follows: Section "Motivation and Fundamentals" discusses in detail the theoretical motivation explaining why these methods should work and presents a significant example in which the majority vote of three classifiers does not induce a more accurate model. Following, will be discussed an example presenting the main issues when combining multiple classifiers; Section "Building an Ensemble Learning System" presents the most commonly used methods to combine multiple models. Finally, Section "Conclusion" concludes the article.

Motivation and Fundamentals

Among other theoretical reasons for supporting ensemble methods, Dietterich *et al.* (2000) gives three fundamental reasons: a *statistical* reason, a *computational* reason, and a third *representative* reason.

The *statistical* reason starts from the assumption that, indicating with L^* the optimal model for a given problem, because of lack of sufficient data, the learning algorithm can find multiple models having the same accuracy. The ensemble approach avoids the problem of choosing between these models by replacing an “average” aggregate model that may be closer to L^* , or have better performances on new data than the single models.

But even if the dataset has a sufficient number of data, it is demonstrated that for some machine learning algorithms the search for the optimal model L^* can be a computationally difficult task (e.g., NP-hard), as many algorithms rely on techniques of local optimization, that can converge towards a local optima. For this reason, a second computational motivation arises from the possibility of building an ensemble in which the local search starts from different points, in order to achieve a better approximation.

The latest motivation, the most subtle, is related to the fact that the optimal solution L^* for the real problem may not be represented by any model in the space of solutions. In this case, the multiple combination of algorithms can lead to a better approximation, for example a nonlinear optimal model can be approximated by a combination of linear models.

Before tackling in detail the methodologies and techniques of ensemble methods, it is useful to resume the analogy with the decision-making board mentioned in the Introduction.

Intuitively, it is clear that in order to form a good committee a first feature to be considered is the independence of the members. Indeed, if the committee is composed of elements that “influence” each other or that analyze the same aspects of a problem, the final decision will not be much more accurate than the decision taken individually by the members. If, on the contrary, the committee is composed of “independent” elements, or, roughly speaking, the members make mistakes on different data, it is expected that the other members of the committee will compensate for the mistake made by the individual member.

As mentioned in the introduction, this intuitive concept finds a theoretical validity in Condorcet’s *Jurys Theorem*. Let consider a jury formed by a group of n people having a probability p of voting correctly and a probability $1-p$ to vote incorrectly; the theorem states that if: (i) each member of the jury has a probability $p > 0.5$ and (ii) the members vote independently of each other, then the probability that the combined vote (in this case a majority vote) is correct tends to 1 as the number of voters increases.

Roughly speaking, the Condorcet’s Jury Theorem states that a jury whose jurors vote independently and have an individual competence greater than 0.5 (and we can consider them weak or strong experts), then the probability that the jury’s vote is correct tends to the certain event as the number of voters increase.

Looking at the problem from another point of view, let’s consider a binary classification problem and n generic C_i classifiers with $i=1..n$ having an error rate lower than the random guessing model, i.e. $err_{base,i} < err_{rand}=0.5$ for $i=1..n$. Under the assumption that the classifiers are independent, that is, their error rate are uncorrelated, then the probability distribution of the ensemble error rate follows a binomial distribution. In particular, if we set $n=9$ and $err=0.3$ and we suppose that the output of the ensemble model is given by the outcome having the majority vote of the base learners, then the probability that the ensemble classifies an element incorrectly is given by the probability that $\lfloor n/2 \rfloor + 1$ classifiers vote incorrectly, or in this case:

$$\begin{aligned} ens\ err &= \sum_{k=\lfloor n/2 \rfloor + 1}^n \binom{n}{k} err_{base}^k (1 - err_{base})^{(n-k)} \\ &= \sum_{k=11}^{21} \binom{21}{k} (0.3)^k (0.7)^{(21-k)} \\ &= 0.0988 \end{aligned}$$

that is the ensemble error is significantly lower than the base error rate.

In the [Fig. 1](#) the relationship between base learning errors and the resultant ensemble error is shown for an error rate in a range between 0 and 1 and considering different number of base learners. It can be seen how, under the assumptions of the Condorcet theorem, i.e., when $0 \leq Base_{err} < 0.50$, the curve lies below the bisector of the first quadrant meaning that the Ensemble error rate is lower than the single classifiers error. Also, as the number of “weak” classifiers increases, for $0 < err < 0.5$ it is evident that the ensemble error curve reaches zero faster.

This example gives an idea of how in ideal situations the use of ensemble learning approach can give very effective results.

However, a basic hypothesis that is used in this example is the assumption of independence of base learners from each others or, in other words, that the errors of base classifiers are not correlated.

Lets now consider the example of three dichotomic classifiers all having probabilities $p=0.6$ to classify correctly and, consequently, and error rate of $err=0.4 < 0.5$. This means that, considering 5 instances, each of the three classifiers makes two mistakes.

The [Table 1](#) shows the combinations of the different outcomes and the last column shows the majority vote accuracy for each combination of the three basic learners. As it can be seen from the table, only in two cases out of 16 the accuracy of the ensemble model is greater than the accuracy of the single classifiers, in 13 cases the accuracy of the combined model equals the accuracy of the single classifiers and in a case out of 16 the accuracy of the individual classifiers is greater than the ensemble model.

classifiers is greater than the ensemble model. Averaging the accuracy of the 16 cases considered, it results that the combined model has a probability $P=61.25\%$ that the majority vote output is correctly classified, i.e., the combined model improves the probability of individual classifiers in average of the 1.25% at the expenses of an increased complexity due to a training and testing phase for all three classifier and to the calculation of the majority vote for each instance.

Fig. 1 The figure shows the error rate of three ensemble classifiers when combining 9 (in blue), 15 (in green) and 31 (in red) classifiers respectively. The x axis represent the single classifier error while the y axis represent the ensemble error. The bisector show the error rate of the random guess algorithm. It's easy to see that when each single classifier's error is lower than the random guessing error, then the ensemble error is lower than the single classifier's error and it tends to decrease to zero more faster when the number of classifier grow.

Table 1 The Table reports the possible output's combination of 3 classifier each of which correctly classifies 3 instances out of 5. Indicating with 1 or 0 if that classifier has classified correctly or it has misclassified that instance respectively, in the first row all the possible combination of the three classifiers' outputs are shown. The penultimate column shows for each case the accuracy rate when the classifiers are combined by a majority voting, and in the last column are reported the differences between the ensemble and the base learners accuracies. In the last row the overall accuracy of the ensemble classifier and the overall improvement with respect to the base classifier accuracy are reported

Possible outcomes										
	111	101	110	0 11	100	0 1 0	0 0 1	0 0 0	p_{ens}	$p_{ens} - p$
0	111	101	110	0 11	100	0 1 0	0 0 1	0 0 0	p_{ens}	$p_{ens} - p$
1	3	0	0	0	0	0	0	2	0,6	0
2	2	1	0	0	0	1	0	1	0,6	0
3	2	0	1	0	0	0	1	1	0,6	0
4	2	0	0	1	1	0	0	1	0,6	0
5	2	0	0	0	1	1	1	0	0,4	-0,2
6	1	1	1	1	0	0	0	1	0,8	0,2
7	1	1	1	0	0	1	1	0	0,6	0
8	1	1	0	1	1	1	0	0	0,6	0
9	1	0	1	1	1	0	1	0	0,6	0
10	1	0	1	1	1	0	1	0	0,6	0
11	1	1	0	1	1	1	0	0	0,6	0
12	1	1	1	0	0	1	1	0	0,6	0
13	1	2	0	0	0	2	0	0	0,6	0
14	1	0	2	0	0	0	2	0	0,6	0
15	1	0	0	2	2	0	0	0	0,6	0
16	1	1	1	1	0	0	0	1	0,8	0,2
									0,6125	0,0125

This unsatisfactory result is due to the non-diversity of the three classifiers, in the sense that they often commit the same mistakes on the same instances, and it follows that the error rates made by the three classifiers are somewhat correlated, against the hypotheses previously made.

Therefore the diversity request is very important for combining multiple classifiers or, in general, multiple learners. The next section will focus on the techniques used to do this.

Building an Ensemble Learning System

In the above example, it has been shown how the diversity of outputs of the classifier base greatly influences the performance of the assembly.

Although the concept of diversity is intuitively simple, in practice it is difficult to define a measure that expresses how “different” are learner.

For this reason, in addition to explicit approaches, in which to construct an ensemble, measures are taken to ensure the diversity of learners, also ensemble constructive approaches have been developed that are based on implicitly inducing diversity among learners, or without recourse to the calculation of a measure of “diversity”.

In Fig. 2, is generally represented the process of building an ensemble model. It can be seen how the diversity of learners base can be introduced at different levels, leading to different ensemble methods. For simplicity, let us now consider classification problems, but the following examples can easily be adapted to the case of generic learners:

- Variations in data: Starting from the initial dataset, different sub-sets are built and each one is trained in a single basic classifier;
- Variations of features: Through feature selection techniques, several feature sub-sets are built on which the classifiers are trained;
- Variation among learners: different classifiers are used (most of these approaches are explicit in that it is required that the classifiers be different). Alternatively, the same algorithm can be used setting different parameters, for example varying the k in kNN algorithm the kernel function in SVM etc;
- Variation in combinations methods: models are combined using different techniques that will be detailed in the next section;
- Variation in output labels, for example using the error correcting output code (ECOC).

Methods for Combining Multiple Learners

The approaches for combining multiple learners can be roughly divided into two groups: a fusion-type strategy, where the combination strategy is expected to consider that, for each instance, each model’s output contributes to the output of the ensemble, and a selection-type schema, in which each learner is supposed to be an “expert” in a specific domain, therefore the output of the induced pattern contributes to the output of the ensemble only for the elements of that domain. There are also combined strategies. Concerning fusion strategies, these mainly depend on the type of learner that constitute the ensemble. Below some of these approaches are presented, again considering only classification problem for sake of simplicity.

Fig. 2 A general Ensemble process representation. A variation at each different level can inject diversity in the construction of the ensemble’s classifiers.

Combining class label

Majority voting

In majority voting, given an instance, its final prediction label is given by the class having the highest number of concordant predicted labels of the individual base classifiers. There are three possible cases, as shown in the Fig. 3: all the classifiers agree on the forecast (unanimity vote), half plus one of the classifiers agree on the prediction (majority voting that can be applied only to dichotomic classifiers), or the largest number of classifiers agree on the prediction (plurality vote).

Let consider a classification problem, with label set $L = \{L_1 \dots L_m\}$ and N classifier $\{C_1 \dots C_N\}$. For each instance i let consider

$$\chi_{L_k}(C_j(i)) = \begin{cases} 1 & \text{if } C_j(i) = L_k \text{ with } L_k \in L \\ 0 & \text{if } C_j(i) = L_q \text{ with } L_k, L_q \in L \text{ and } q \neq k \end{cases}$$

then, combining the N classifiers with a majority vote, the ensemble prediction's label can be defined as

$$L_{ens} = \arg \max_{L_k} \sum_{j=1}^N \chi_{L_k}(C_j(i))$$

In this case all the N classifiers' votes have the same importance for the ensemble prediction.

A variant of the majority voting is the *weighted majority voting* in which to each classifier is assigned a weight w_j such that $\sum_{j=1}^m w_j = 1$ and the ensemble prediction label will be

$$L_{ens} = \arg \max_{L_k} \sum_{j=1}^N w_j \chi_{L_k}(C_j(i))$$

Borda count

While in voting given an instance i each classifier can votes only for one class label at time, and the ensemble class label obtaining the highest number of votes is considered, the Borda count approach is to let each classifier give a support rank to each class label, producing a ranking list. Then to each position in the list is assigned a decreasing score (for e.g., the class label occupying the first position in the list gets m vote, while the one in last position gets 1 point). Finally, the class label predicted by the ensemble will be the class label having the highest score overall.

Combining functions for continuous decision outputs

If the learners provides as output a numerical values, i.e. for each instance i the prediction of the j -th learner for $j = \dots N$, will be a value $d_j(i)$ in some range. In this case the most followed approach is to define the ensemble model prediction as an algebraic combination of each learner's prediction, that is

$$d_{ens}(i) = F[d_1(i) \dots d_N(i)]$$

Multiple are the possible choices of the algebraic function F , and some are listed below:

- **Mean rule:** $d_{ens}(i) = \frac{1}{N} \sum_{j=1}^N d_j(i)$
- **Weighted average** $d_{ens}(i) = \frac{1}{N} \sum_{j=1}^N w_j d_j(i)$, for w_j be such that $\sum_{j=1}^N w_j = 1$
- **Minimum rule** $d_{ens}(i) = \min_{j \in [1 \dots N]} d_j(i)$
- **Maximum rule** $d_{ens}(i) = \max_{j \in [1 \dots N]} d_j(i)$
- **Median rule** $d_{ens}(i) = \text{median}_{j \in [1 \dots N]} d_j(i)$
- **Product rule** $d_{ens}(i) = \frac{1}{N} \prod_{j=1}^N d_j(i)$

Fig. 3 A example of unanimity, majority and plurality voting.

Most Popular Ensemble Learning Algorithm

In general, it is evident that the class of ensemble methods is made up of many possible algorithms. However, 4 methods can be considered the most representative, namely: Bagging, boosting, Stacking and cascading.

In *Bagging*, i.e., Bootstrap AGGREGATING, n models $M_1 \dots M_n$ are constructed by applying a base learning algorithm A to n bootstrapping sample $D_1 \dots D_N$ (i.e., random samples with replacement) of the dataset D . The n models are then combined with a majority vote. For bagging to be effective, it is expected that small perturbations in the D_i samples produce large variations in the M_i models. Formally, it can be said that bagging is effective for *unstable* algorithms.

Boosting is a method that explicitly induces the diversity among the learners of ensembles, as it aims to maximize the accuracy of an algorithm on the set of instances in which previous models fail.

Lets consider the case of a classification problem. As for Bagging, the first Classifier C_1 is trained on a random sample of the Training Set producing an M_1 model. The second classifier C_2 is trained on a set datasets subset composed by 50% of instances correctly classified by the first classifier and by the other 50% by misclassified instances of the first classifier. A third M_3 model will then be built by training a third C_3 classifier on the subset of the dataset on which the M_1 and M_2 models disagree, and so on. Models thus produced are combined with a majority vote.

Two are the major differences between the previous methods and *Stacking*: the first is that if Bagging and Boosting follow the approach of varying the training set, stacking applies a variation a the algorithm level, i.e. diversity is built by using different algorithms; the second difference is that in stacking methods, models are combined through a Meta-Learner applied on a Meta-dataset containing for each instance the predictions of each base model.

Lastly, with the *Cascading* method, the ensemble is built by applying different algorithms like stacking and by varying the distribution of instances on the training set as with saw in boosting. However, the cascading method follows a multistage scheme, in which as long as an instance I_k is classified by a model M_i (induced by the classifier C_i) with a confidence rate lower than a defined threshold, it is more likely that instance I_k will be selected to be classified by a classifier $C(i+1)$, having a greater complexity than the classifier C_i .

Conclusion

In this article, the theoretical foundation of combining multiple learner's theory is discussed. In particular, through examples it was shown why one of the most important requests for building a good ensemble is that the base learners has to be "weak" expert and, moreover, they have to be "diverse" in a given way. Then, the most used function for combining learners' output and a brief overview of the most used ensemble approaches were presented. In the next articles each of there approaches will be discussed in details.

Multiple Learners Combination: Bagging

Chiara Zucco, University "Magna Graecia" of Catanzaro, Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

The development of omics sciences has led to the introduction of methodologies in order to identify, from experiments such as mass spectrometry and microarray, genes involved in a given disease. A bioinformatic approach to this problem involves the application of Machine Learning methods, for example in relation to microarray data or in gene-gene interactions, enabling high-performance analysis procedures.

In particular, the tasks of classifying and predicting genes that can discriminate particular tissue types, has been shown to play a central role for the effective diagnosis of cancers and other diseases.

Unfortunately, there not exist a classification algorithm, and in general, a machine learning algorithm, that always induces the most accurate model. For this reason, in order to improve the accuracy of the model, instead of searching for the best machine learning algorithm, an alternative can be to combine multiple learners having an accuracy slightly greater than random guessing.

These methods, also called ensemble learning methods, take inspiration from real life phenomenon like democratic process, expert teams etc. and, under suitable conditions, have shown to achieve valuable results, see for example [Kuncheva \(2004\)](#); [Polikar \(2012\)](#); [Dietterich et al. \(2000\)](#); [Duda et al. \(2012\)](#).

As will be discussed below, a key point in dealing with ensemble methods is that the base learners (that is, the learners composing the ensemble) have to be chosen or built in order to make different mistakes on different instances of the data set or, in other words, by implicitly or explicitly increasing the diversity between them.

One of the simplest yet effective ensemble approach is Bagging, standing for Bootstrapp AGGREGatING, and presented by [Breiman \(1996a\)](#).

In Bagging As the name suggests, in Bagging ensemble algorithm the base learners are built by training the same algorithm on different training sets, obtained as bootstrap samples of the original training set. In Bagging diversity is therefore enhanced implicitly.

There also exist variations of Bagging, the most popular of which is Random Forest, introduced by [Breiman \(2001\)](#).

Bagging and Random Forest found wide applications for improving accuracy in microarray data prediction.

One of the first work in this sense was done in [Ben-Dor et al. \(2000\)](#), while Tan and Gilbert first prove that ensemble learner can improve the coverage of the protein fold classification classifiers of a multi-class imbalanced sample ([Tan et al., 2003](#)), and then performed a comparative study of bagged and boosted decision trees over a single decision tree algorithm, for the classification of seven cancerous microarray dataset, showing that ensemble methods effectively improve the performances of a single decision algorithm ([Tan and Gilbert, 2003](#)). Another comparative study was carried out in [Wu et al. \(2003\)](#), where bagging boosting and random forest performances were compared with single classifiers such as kNN, SVM and others. The algorithm were evaluated for classifying ovarian cancer from mass spectra serum profiles and results shown that random forest achieved, on average, the lowest error rate.

These are only few among the examples on how successfully Ensemble methods and, in particular, bagging can be applied in bioinformatics, although an extensive review of studies in this field is beyond the purpose of this work.

The aim of this article is twofold: to provide the underlying fundamentals of Bagging and to present the Bagging and random forest algorithms.

In particular the starting points of this discussion will be resampling techniques and some theoretical results involving two variables useful for measuring the performances of a model and the relation between the to of them and the error rate. This is known as *bias-variance tradeoff/dilemma* and will be discussed in Section "Motivation and Fundamentals", while in Section "Bagging and Random Forest" will be outlined the step for constructing a bag of classifiers.

Motivation and Fundamentals

In this section some background information are provided. In particular, some theoretical results underlying machine learning algorithm are discussed and some resampling techniques are presented, dealing with their effect on a classification problem.

The Bias-Variance Trade-Off

When dealing with a classification or a regression problem, in addition to error due to noise in data, two are the main variables that can affect the performances of a model induced by a machine learning algorithm:

- Bias, that is, the measure of how the prediction model differs from the real value, in other words how the model is accurate.
- The variance, i.e., the measure of how much the model is sensitive to slight changes in the training set.

Although there are designing techniques devoted to adjusting the algorithm and reducing bias or variance, it will be shown below that bias and variance are not independent of each other but respond to a same relationship, called Bias-variance decomposition.

For sake of simplicity, a regression problem is considered in the following.

Let consider an arbitrary but fixed training set $\mathcal{D}$ and let $f(x)$ be a continuous valued function representing the unknown solution (also called true function) for the regression problem. Let $r_{\mathcal{D}}(x) = r(x, \mathcal{D})$ be the function modelling the regression problem or, that represents an estimation for $f(x)$.

In order to judge the quality of this estimation on $\mathcal{D}$, a useful theoretical measure is given by the *mean squared error*, i.e., the second moment of the deviation or, in other terms, the expected value of the quadratic error, $E[r_{\mathcal{D}}(x) - f(x)]^2$.

Applying well known properties of the expected values, the mean squared error can be expressed as

$$\begin{aligned} E[(r_{\mathcal{D}}(x) - f(x))] &= \underbrace{E[(r_{\mathcal{D}}(x) - f(x))]^2}_{bias^2} + \underbrace{E[(r_{\mathcal{D}}(x) - E[r_{\mathcal{D}}(x)])^2]}_{variance} \\ &= \quad \quad \quad + \end{aligned} \quad (1)$$

and it's known as the bias-variance decomposition [Sammut and Webb \(2011\)](#), [Duda et al. \(2012\)](#). Eq. (1) shows a general problem of machine learning: the more the model adds degrees of freedom to better adapt to data (low bias), the more it's sensitive to perturbation in the dataset (high variance) and this problem is referred to as *overfitting*. On the contrary, the lower are the degrees of freedom for the model, the greater will the sensitivity of the model, with a consequent "poor" adapting to data (underfitting). For example, if we consider as true function $f(x) = \sin(3\pi x)$ with noise, aiming to estimate $f(x)$ on a training set $\mathcal{D}$ of 15 points, with polynomial functions of degrees 1, 3 and 15 respectively. In [Fig. 1](#) is shown how the increase of the degrees of freedom tends to minimize the bias, fitting better the data, but incrementing the variance.

Of course, the ideal solution is to build a model having low bias and low variance (bias-variance trade-off).

Resampling Techniques

After introducing bias and variance, the next step is to determine these measurements to evaluate the performance of a learning algorithm for problems with unknown distribution. A class of statistical techniques useful in this context is called resampling. In particular, the focus will be made to the Bootstrapping that is a resampling technique that is also used for constructing the training subsamples on which the classifiers are trained in Bagging.

Bootstrap resampling

The term *Bootstrap* is referred to the resampling techniques of randomly selecting from a dataset $\mathcal{D}$ with N -cardinality, a set of $n \leq N$ instances with replacement. In the next Section it will see that this process can be repeated in order to generate m bootstrap dataset.

Example 2.1: Let now consider a set $\mathcal{D}$ of $n=N$ distinct values, then the bootstrapping process can generate $(2N - 1)$ distinct subsets. Moreover, in this case each instance of the dataset has probability $\frac{1}{N}$ of being randomly selected to populate the j^{th} subset, and has a probability $1 - \frac{1}{N}$ of not being selected. Therefore, each instance i has probability $P_N = (1 - \frac{1}{N})^N$ of not appearing in the j^{th} bootstrapped subset. As N increases, $P_N \rightarrow \frac{1}{e}$ that is, approximately, $\frac{1}{3}$ of the original dataset.

In the *balanced bootstrap sampling* the generation of the bootstrap sets takes into account also the request that the instances of the original dataset have to be present a number of time that is exactly the number m of generated bootstrap sets. This means that if an instance is present with repetition in a training subset, there will be another training subset in which that same instance will not appear. Balanced bootstrap samples are generated starting from a set with copies for every m instances, and then randomly altering the starting dataset by adding or deleting instances.

Fig. 1 The Figure shows how increasing the degrees of freedom, the curves estimating the true function $f(x)$ tends to fit more the data points (low bias) and to increase the oscillation (high variance).

A bias-variance decomposition holds true also in classification fields but here the proof is more subtle, because in this case can be shown that the relationship between the estimated error and the couple bias-variance isn't linear anymore but becomes multiplicative.

A last example shows how averaging behaves on bias and variance.

Example 2.2: Let d_j for $j=1\dots m$ be independent variables identically distributed (i.i.d.) and, therefore, having $E[d_j]$ as expected values. Let y be the variable obtained by averaging d_j for $j=1\dots m$. Then

$$E[y] = E\left[\sum_{j=1}^m \frac{1}{m} d_j\right] = \frac{1}{m} E\left[\sum_{j=1}^m d_j\right] = E[d_j]$$

and

$$Var(y) = Var\left(\sum_{j=1}^m \frac{1}{m} d_j\right) = \frac{1}{m^2} Var\left(\sum_{j=1}^m d_j\right) = \frac{1}{m} Var(d_j).$$

From the last series of equivalence, it can be seen that the variance of y decreases as the number of m increases without increasing the bias that, due to the i.i.d. hypothesis, remains stable. As a consequence, also the error decreases.

Applying an averaging function leads to lower the variance also when the variables $\{d_j\}$ are negatively correlated but, in this case, the bias tends to increase. On the contrary, if the variables $\{d_j\}$ are positively correlated, averaging leads to an increment of both variance and error.

Bagging and Random Forest

The Bagging Algorithm

The idea underlying bagging is related to the example of the last Section, that is to construct an ensemble of independent model with high variance and low bias and then to average over that models in order to decrease the variance without significative effects on the bias.

Bagging, as the other ensemble learning methods, can be seen as composed by two steps: in the first one, the single learning models are generated, in a way that can emphasizes diversity, and consequently keeping the correlation among models low; in the second step, the models are combined, generally by using a combining function.

Fig. 2 A bagging process representation.

Specifically, referring to a classification on a numerical prediction problem, in bagging the models that will constitute the ensemble, are built by training the same learning algorithm on m subsets generated from the training dataset $\mathcal{D}$ by applying a balanced bootstrap samples process.

Then, the same test set will be used for testing every model and the ensemble prediction is finally obtained by a majority voting for a classification problem and by averaging on the models' output in numerical prediction.

As stated in the introduction, Bagging is one of the most simple ensemble methods, but yet can perform with outstanding results when used with *unstable* learners.

An unstable learner is a machine learning algorithm whose generated model tends to respond to slight changes in the training set with significant changes in the model. Therefore, it is clear that unstable learners trained on m bootstrap samples produce m different models, ensuring in general the diversity required for improving the overall accuracy. In reality, this is true only for not large training set.

Below, the pseudo-code for bagging is illustrated in [Algorithm 1](#), while [Fig. 2](#) summarizes the bagging process.

Algorithm 1: Bagging algorithm.

1 Models generation

2 Initialize the parameters:

- the ensemble $\mathcal{E} = \emptyset$;
- the number n of instances of the training data;
- the number m of learners;
- the algorithm $\mathcal{A}$;
- a set of prediction $P_1, \dots, P_q$;

For $j = 1 \dots m$:

- generate a bootstrap sample $\mathcal{D}_i$ instances from the training set;
- build the learner $\mathcal{C}_i$ training $\mathcal{A}$ on $\mathcal{D}_i$;
- add the learner $\mathcal{C}_i$ to the learner set, $\mathcal{E} = \mathcal{E} \cup \mathcal{C}_i$;
- return $\mathcal{E}$;

Testing

Apply $C_1 \dots C_m$ on the new instance $\mathbf{i}$ calculating the predictions $C_j(\mathbf{i})$

Calculate the ensemble prediction by:

$$P_{\mathcal{E}} = \arg \max_k \sum_{j=1}^n \chi(C_j(\mathbf{i}) = P_k)$$

Randomization

The strength point of bagging is to implicitly address the complex problem of the model diversity, by inducing randomness in the training subset of the learning algorithm and then taking advantage of the instability of the base learner. For example, an ensemble built using as base learner a stable algorithm as nearest neighborhood it will lead an increase in complexity without substantial improvement in performances.

Another issue of using bagging alone, is that the level of diversity achieved are lower if compared to other approaches and can be further increased only by combining bagging with other techniques.

Indeed, in general there are also other approaches for injecting randomness within the algorithms, especially in case of algorithms that have an embedded random component. In this cases, starting from a base learning algorithm, the idea is to obtain the ensemble learners from the base learner by random varying some parameters, for example the initial weights in neural networks, or in decision tree algorithm by randomly selecting the attribute from a list of best attribute in order to split-on at each node.

When dealing with randomization the goal is to increase diversity between learners but the risk is to obtain a significant decrease in the single learner's accuracy. Moreover, injecting randomness in general requires modifications in the learning algorithm, while it can lead benefits also with stable base algorithms.

An idea is to combine bagging with randomization technique in such a way they can complementary level of randomness and, therefore, emphasize the diversity among learners. An example of how this combination can bring to excellent results is *Random forest*.

Random Forest

Random forest is a variant of bagging in which the base learner is a decision tree, proposed by [Breiman \(2001\)](#). Below, is given a formal definition:

“Let $v_1, \dots, v_m$ be i.i.d. vectors. A random forest is a classifier built by combining through majority voting m decision trees $T_1, \dots, T_m$ grown with respect to $v_1, \dots, v_j$ respectively”.

So each random tree of the random forest can be grown by considering the bagging procedure of bootstrap subsampling of the training set, a random subsample from the features set, by varying some parameters or by a combination of these approaches. In order to alleviate the “course of dimensionality” in high-dimensional dataset and to improve the diversity among the decision trees of the ensemble, a common approach is to build each decision tree on a different bootstrap sample and on a different subset of features, without replacement.

The random forest algorithm can be summarized in few steps:

- Generate a bootstrap sample $\mathcal{I}$ of dimension n from the training set $\mathcal{D}$.
- For each $i = 1 \dots m$ grow the i -th decision tree by randomly selecting q features without repetition and then splitting the node based on the best feature. Supposing that the Feature set contains Q features, a common used value for setting the dimension of the features' subset is $q = \sqrt{Q}$.
- Combining the prediction by a suitable combination function (such as Majority vote for classification problems and by averaging prediction in regression problems).

One of the advantages of random forests compared to decision tree model is that, in this case, each decision tree grows with bootstrap samples of the original training set and with a subset of different features for each tree, then the generated model is more robust and less susceptible to overfitting, and this is the reason for which, in general, it's not required to prune the random forest. As previously mentioned, even averaging function and majority voting methods tend to further decrease variance without significant bias repercussions.

The pseudocode of the Random Forest algorithm is shown below 2.

Algorithm 1: Random Forest algorithm.

1 Random Forest generation

2 Initialize the parameters:

- the Forest $\mathcal{F} = \emptyset$;
- the Dataset $\mathcal{D}$;
- the set of Feature $\mathcal{F}$;
- the number m of trees in the forest;

For $i = 1 \dots m$:

- generate a bootstrap sample D_i of instances from $\mathcal{D}$;
- build the i -th tree $T_i = \text{tree}(D_i, \mathcal{F}_i)$:
 for each node:
 generate a subset F_i of feature from $\mathcal{F}$ without repetitions;
 split the node using the best feature;
 return $\mathcal{T}_i$
- generate a subset F_i of feature from $\mathcal{F}$;
- add the tree T_i to the forest, $\mathcal{F} = \mathcal{F} \cup T_i$;
- return $\mathcal{F}$;

Combining Prediction's trees

For each instance i calculating the predictions $P_j = T_j(i)$

Calculate the ensemble prediction by

$$P_{\mathcal{F}}(i) = \text{Average}(T_1, \dots, T_m, i) \text{ OR}$$

$$P_{\mathcal{F}}(i) = \text{Majority vote}(T_1, \dots, T_m, i)$$

Out-of-Bag Error

As seen in the example 2.1, each algorithm composing the ensemble learner is trained on a bootstrap subsample $\mathcal{D}_i$ containing, on average, the 64% of instances from the original training set $\mathcal{D}$, while the remaining 37% of instances of each subsample are replicated instances. Another 37% of instances belonging to the original training set do not belong to $\mathcal{D}_i$ and are called “out-of-bag” instances. So, when the number of instances of the dataset is suitable to be divided in training set, Out-Of-Bag (OOB) set and test set, the idea is to use the OOB instances predictions in order to have efficient estimates of the generalization performances of Bagging ensemble. The OOB error can be obtained by averaging the generalization estimates of all the learners of the ensemble. In particular OOB instances have been used to provide estimates of node probabilities and error rates for each tree of the random forest or, in regression trees, it was seen that by replacing OOB estimated prediction instead of the observation outputs can improve performances Breiman (1996b).

Conclusions

In this article the basic concepts of Bagging algorithms were introduced, with particular focus on theoretical background and on the motivations thanks to which Bagging ensemble algorithm and its variant can improve prediction problems.

Multiple Learners Combination: Boosting

Chiara Zucco, University of Magna Græcia of Catanzaro, Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Boosting is an iterative procedure for combining multiple learners, easy to implement and extremely powerful and, for this reason, represents an important element in the repertoire of learning mechanisms.

Since we will pose accent on supervised learning algorithm, besides the word learner, it will be also used the terms classifier or predictor.

A multiple learner combiner, also known as ensemble learner, can be viewed as a committee of learners whose predictions are combined in a suitable way to achieve better performances than any single learner in the committee, see Polikar (2012) and Alpaydin (2014).

Another way to see an ensemble learner method is as a procedure that allows to build a strong learner (having high performances in sense that we will formulate in the following) starting from a set of base or weak learners (slightly better than random guessing).

Two are the fundamental points in constructing an ensemble learner:

- To choose or build base learners to make different mistakes on different instances of dataset, by enhancing diversity among them;
- To choose a suitable rule for combining each learner's output.

As previously seen, if in Bagging diversity among learners is enhanced in an implicit way by training in parallel the same algorithm on n bootstrapped replicates of the training sample, the idea behind Boosting is to train learners in a sequential fashion, boosting the subsequent learner by acting on the training sample distribution and increasing weights on instances that were predicted wrong by the previously trained learner, see Kuncheva (2004) and Breiman *et al.* (1998).

The history of Boosting followed somehow a special way from that of the other ensemble algorithms. In fact, boosting finds its roots in the Computational learning theory and in particular in the Probably approximately correct learnability (PAC-learnability) framework, the first theoretical learning model presented by Valiant (1984). In particular, the first idea of "boosting" was proposed by Kearns (1988), while Schapire (1990), presented a first "Boosting" algorithm as a recursive process to show the equivalence of two sets of PAC-learner sets: strong learner and weak learner. A year later, Freund (1995), starting from the work of Schapire, proposed a non-recursive algorithm and introduced a majority-vote function for combining the weak learner's outputs. These approaches were both suffering of some practical drawbacks and, working together in the following years, Freund and Schapire (1995) presented an algorithm, called AdaBoost, thanks to which they won the Gödel award, one of the highest recognitions in theoretical computer science. Although Boosting can be considered as a family of algorithms, since there are many variations and "specializations" of Boosting, see Schapire and Freund (2012), AdaBoost still remains the boosting algorithm most used in practice, thanks to its simplicity and versatility.

In this article, Adaboost is introduced, trying to indicatively follow the path just described. In particular, in Section "Background and Fundamental" some basic principles of PAC-learnability are laid out and the classes of weak and strong learners are introduced. Following, a first approach to Boosting is presented, while in Section "Adaboost" AdaBoost is presented.

Background and Fundamental

In order to roughly explain the core idea of PAC-learnability, let's consider the following example.

Suppose that a buyer B who is looking for a new home, goes to a real estate agent E to find out what is the house price range of a specific neighborhood. The agent does not directly disclose the price range $[a, b]$, but he provides some examples by generating at random house prices by following a fixed way (or Distribution), and showing the buyer the value of that random price, let's say x , and a label y , that is saying if that house price x belongs to the house prices range of the neighborhood (positive examples, labeled as $+1$) or if it doesn't (negative examples, labeled as -1). Since E only provides finitely many examples and being a and b in general real numbers, B can not exactly determine the extremes of the interval. Therefore, from the examples provided by E, the objective of buyer B is to give an answer that is close enough to the real interval $[a, b]$, i.e., an approximation $[c, d]$.

For each real interval considered, it is possible to calculate the probability that, as the number of examples given by E increases, the range indicated by B does not represent a good approximation for $[a, b]$, and therefore that B will give an incorrect answer. If this probability is appropriately "small" or, in other words, if the error between the real range and the approximation given by B has high probability to be very small, it can be said that B has learned the interval. Assume then that this experiment is repeated several times, varying the interval and the strategy or distribution used by E for generating prices. If every time B finds, with high probability, a good approximation for the interval, it can be said that the problem is Probably Approximately Correct (PAC)-learnable.

With this example in mind, we can provide some formal definition.

Let X be a set or domain, also called *instance space* and $Y = \{-1, +1\}$ be a set of labels. It is assumed that there exist some probability distribution D , generating couples (x, y) . We assume that there also exists a *target function* $f: X \rightarrow Y$ be such that, for each (x, y) extracted from the distribution D , the following:

$$\mathbf{P}_{(x,y) \sim D}[y = f(x)|x] = 1$$

holds true, that is the examples are in the form $(x, f(x))$.

Let's suppose that to a learning algorithm A are given some *labeled examples* (x_i, y_i) , generated by the unknown distribution D . Starting from A , the goal is to construct a *learner* h (also called hypothesis, or model, or classifier) that, having access to the labeled examples generated by D , can approximate the target function f with high probability.

Given a learner $h: X \rightarrow \{-1, +1\}$ with respect to a target function $f: X \rightarrow \{-1, +1\}$ and the distribution D , the *error* is defined as

$$\text{err}_{f,D}(h) = P_D(h(x) \neq f(x))$$

We now give the definitions for an algorithm to be a strong or weak learner. For further details, see the works of [Valiant \(1984\)](#) and [Schapire \(1990\)](#).

Definition 2.1: Let X be a domain with size n and let $\mathcal{F}$ be a family of target functions $f: X \rightarrow \{-1, +1\}$. An algorithm $A = A_{\epsilon, \delta}$ is said to **strong PAC learn** the family of target functions F over the domain X if, for any target function $f \in \mathcal{F}$, for any distribution D over X and for any $0 < \epsilon, \delta < 1/2$, it holds true

$$\mathcal{P}_D(\text{err}_{c,D}(h) \leq \epsilon) > 1 - \delta$$

i.e., the model h built by the algorithm A has error at most ϵ with probability at least $1 - \delta$. Moreover, A must run in polynomial time in $\frac{1}{\epsilon}, \frac{1}{\delta}$ and n .

An algorithm that strong PAC learns A family F of target functions on X is said to be a *strong learner*.

Another important class of learner is the class of *weak PAC-learners*, introduced in the following.

Definition 2.2: Let X be a domain with size n and let $\mathcal{F}$ be a family of target functions $f: X \rightarrow \{-1, +1\}$. An algorithm $A = A_{\epsilon, \eta}$ is said to **weak PAC learn** the family of target functions F over the domain X if, for any target function $f \in \mathcal{F}$, for any distribution D over X and for any $0 < \delta < \frac{1}{2}$, and for some fixed $0 < \eta < 1/2$ it holds true that

$$\mathcal{P}_D\left(\text{err}_{c,D}(h) \leq \frac{1}{2} - \eta\right) > 1 - \delta$$

i.e., the model h built by the algorithm A has error which is slightly better than random guessing, with probability at least $1 - \delta$. Moreover, A must run in a polynomial time in $\frac{1}{\epsilon}, \frac{1}{\delta}$ and n .

An algorithm that weak PAC-learns A family F of target functions on X is said to be a *weak learner*.

Schapire roughly defines a weak learner as a “rule of thumb”, a rule that can be easily learned and applied but not accurate, most based on practical experience rather than theory. As example of this “rule of thumb” we can consider a decision stump, i.e., a decision tree having just one node and, therefore, in which the tree root is directly connected to the leaves.

The First Boosting, or Boosting by Filtering

As said before, the first version of Boosting was used as a constructive proof of the equivalence of strong and weak learners in free distribution context.

This equivalence naturally means that a concept can be weak-learned if and only if it can be strong-learned.

If the first implication is trivial because if a problem is strong-learned, it means that there exists a strong learner that learns it. But, by definition, a strong learner is also a weak learner, and this show the first implication.

It remains to show that if a concept is weak-learnable then, starting from this weak learner, a strong learner can be built.

The idea of the proof follows two steps:

- A first model, slightly more accurate than the weak model, is built by subsequentially training the same algorithm on three different subset of X , obtained by a suitable filtering methods.
- It is shown that the error can be made arbitrarily small, by recursively applying the first step.

As the whole demonstration is beyond our goals, we will only focus on the first step, that is constructing an algorithm E that simulates the algorithm A on three different distributions (building three different weak models), and then outputs a model H significantly closer to c .

Let A be an algorithm that produces with high-probability a weak learner h' whose error is $\text{err}_{c,D}(h') = \alpha \leq \frac{1}{2} - \eta$ for some fixed $0 < \eta < \frac{1}{2}$. The steps used for sequentially build the model H are the following:

- (1) From the Training Dataset T , with the original (uniform) distribution D , a subset T_1 is extracted. A weak learner h_1 is built by training the algorithm A on T_1 .

- (2) The algorithm A is forced to pay attention to the “harder” parts of the training set T_1 , that is on the examples that were misclassified by h_1 . To do this, a distribution D_2 is built in a way that an instance has equal chance of being correctly or incorrectly classified by h_1 , by filtering from T_1 those instances well classified by h_1 and then adding the same number of instances correctly classified by h_1 and a new training set T_2 is built starting from D_2 . A second weak learner h_2 is the model output of training A on T_2 .
- (3) Finally, a third weak learner h_3 is built by training A on a set T_3 containing instances on which models h_1 and h_2 disagree, with T_3 having a new distribution D_3 constructed by filtering from D those instances on which h_1 and h_2 agree.
- (4) At last the model H , output of E follows this rule:

$$H(i) = \begin{cases} h_1(i) & \text{if } h_1 = h_2 \\ h_3(i) & \text{if } h_1 \neq h_2 \end{cases}$$

It can be found that a bound for the error h is given by the function $err(H) \leq 3\alpha^2 - 2\alpha^3$ and, being $\alpha < \frac{1}{2}$ it follows that the error of H is smaller than α .

Adaboost

Unlike the constructive algorithm presented in the previous section where starting from a subset T , the following model was the result of training on a new subset obtained from the previous through a filter operation, in AdaBoost every weak learner is trained on the whole training set T . In order to encourage the weak learner of step $k+1$ to pay more attention to the instances that have been misclassified in step k , the distribution associated with the dataset is updated at each iteration and, consequently, the weights given to each attribute are updated, so that the outputs of the models are combined through a weighted majority vote.

AdaBoost stands for **ADaptive BOOSTing**, in the sense that the distribution of the dataset on which to train the algorithm A, is adaptively modified at each iteration, on the basis of the misclassified outputs.

Before introducing Adaboost's pseudocode, let's see with a well known example how this algorithm works. Let's consider a dataset T , composed by 10 instances, five of which are positive (shown with red points) and the remaining 5 are negative instances (shown in blue). And suppose to perform a binary classification. At a first step, the distribution of the dataset is uniform, so each point in the figure has equal weight $\frac{1}{10}$. On this set is trained a decision stump. The model M_1 is shown in Fig. 1, step1, subfigure A). At the second step, the distribution of the dataset T is updated (see Fig. 1, Step 2, subfigure 2) in order to train the decision stump to build a second model M_2 that pays more attention to the misclassified points (see Fig. 1, Step 2 subfigure B). At the third step, once again the distribution of T is updated and more weight is given to the three points misclassified by M_2 , then the algorithm is trained on that distorted version of T (see Fig. 1, Step 3, subfigure C). The three models are finally combined by a weighted majority vote, giving the ensemble model shown in Fig. 1 (see subfigure E).

If intuitively the steps of Adaboost are now clear and can be generally summarized in the Pipeline shown in Fig. 2, what remains to be defined is how the distribution D_k is updated at each step. We expect that, for each instance i in the training set T , at step $k+1$, an iterative punctual definition for the distribution function $D_{k+1}(i)$ has to take into account:

- The weight $\alpha_{k'}$ of learner $h_{k'}$, that will depend on the error $\epsilon_{k'}$;
- The punctual distribution defined in the previous step $D_k(i)$;
- The information that the model h_k has correctly classified the instances i or not.

Thanks to the assumption that for each k are defined the functions $f, h_k: X \rightarrow \{-1, +1\}$, it follows that the last information is given by the product $f(i)h_k(i)$, because:

Fig. 1 A classic example of an AdaBoost classifier consisting of three decision stumps (the weak learners), shown in subfigures A, B and C, respectively. At each step, the training subsets distribution is updated, in order to pay more attention to misclassified instances (see subfigures 1, 2, 3). In the final step (subfigure E) the three classifiers are combined through a weighted majority vote.

Fig. 2 A pipeline for AdaBoost algorithm.

$$f(x)h_k(x) = \begin{cases} 1 & \text{if } f(x) = h_k(x) \\ -1 & \text{if } f(x) \neq h_k(x) \end{cases}$$

In order to minimize the training error in the shortest possible time, it can be shown that (see [Freund and Schapire, 1997](#)), for every instance $i=1 \dots n$, a good recursive definition of D_{k+1} is the following:

$$D_{k+1}(i) = \frac{D_k(i)}{Z_t} e^{h_k(i)\gamma_i\alpha_k}$$

where we used that $f(i)=\gamma_i$ for $i=1 \dots n$, and Z_t is a suitable normalization factor for D_{k+1} to be a distribution, α_k is a parameter depending on the error ϵ_k of h_k on D_k . In particular a good choice for α for a binary classification problem is shown to be:

$$\alpha_k = \frac{1}{2} \ln \left(\frac{1 - \epsilon_k}{\epsilon_k} \right)$$

In the following Algorithm [1], a pseudocode for Boosting is presented.

Algorithm 1: *Bagging algorithm*

Input

- The training Set $T=(x_1, \gamma_1), \dots, (x_n, \gamma_n)$ where $\gamma_k \in -1, +1$ for $k=1, \dots, n$;
- The base algorithm A ;

Models generation

Initialize the following parameters:

- The initial distribution $D_1(i) = \frac{1}{n}$;
- The number of generating models m .

For $k=1 \dots m$:

- Build the learner h_k by training A on T using the distribution D_k ;
- Update the error $\epsilon_k = \sum_{i \in T} h_k(x_i) \neq \gamma_i D_k(i)$;
- Update the weights $\alpha_k = \frac{1}{2} \ln \left(\frac{1 - \epsilon_k}{\epsilon_k} \right)$;
- Update the distribution $D_{k+1}(i) = \frac{D_k(i)}{Z_t} e^{h_k(x)\gamma_i\alpha_k}$;

Output

For every x ,

$$H(x) = \text{sign} \left(\sum_{k=1}^m \alpha_k h_k(x) \right)$$

Conclusions

In this article the basic concepts of Boosting algorithms were introduced, with particular focus on theoretical background and on the motivations thanks to which Boosting ensemble algorithm and its famous variant, AdaBoost, can improve prediction problems.

Multiple Learners Combination: Stacking

Introduction

Thanks to the development of more advanced high-throughput technologies, the last decades have seen the data extracted from the omic sciences become more and more numerous to assume the characteristics of “big data”. This is one of the reasons why Machine Learning and Data Mining have become an increasingly used ally in order to analyze this kind of data, especially for prediction and classification tasks.

Of course, the more accurate the models are the better the prediction will be. Unfortunately, there not exist an “oracle” algorithm, always outperforming other learning algorithm in free domains problems (Wolpert and Macready, 1997). Ensemble learning processes raise from the idea that in order to reach better performances, a set of multiple “weak” learner could be combined to form a “strong” learner (Kuncheva, 2004; Polikar, 2012; Alpaydin, 2014).

Stacked generalization, usually referred as Stacking, is an ensemble technique proposed in ‘92 by Wolpert (1992).

Although Stacking is less widely used than Bagging and Boosting, it was also applied in Bioinformatics context. For example in Wang *et al.* (2006), support vector machine and instance-based classifiers were combined using stacked process to predict membrane protein types based on pseudo-amino acid composition. Other application can be found in He *et al.*, (2013), where a stacking process was used for the automatic extraction of Drug-Drug interaction from biomedical literature and to build a decision-based fusion models for the classification of mutation for breast and ovarian cancer in (Sehgal *et al.*, 2004).

In Stacking process, the ensemble learner is generally built by combining models of different types. The procedure can be described as follows:

1. Divide the training set into two disjoint sets,
2. Train different basic “learners” on the first part,
3. Test the basic learnings on the second part,
4. Using the predictions of (3) as input and correct answers as output instruct a higher level learner.

Stacking can be considered an evolution of cross-validation that we’ll see more in details in the following subsection.

Background and Fundamentals

Before discussing the details of the stacking approach in combining multiple learner, in this Section attention is drawn to some preliminary concepts useful in the following, and the basis of constructing an ensemble of machine learning algorithms will be discussed.

Cross-Validation

It’s worth to remember that, in addition to error inducted by noise in data, two are the main variables that can affect the performances of a model inducted by a machine learning algorithm:

- Bias, that is, the measure of how the prediction model differs from the real value.
- The variance, i.e., the measure of how much the model is sensitive to slight changes in the training set.

It can be shown the bias and variance respond to a same relationship, called Bias-variance trade-off.

Models with low bias and high variance have overfitting problems to data while models with high bias and low variance underfit data. It is therefore clear that an important step for constructing a learning model is to estimate its performance.

Cross-validation includes a set of techniques used for the validation of a model or, in other words, to estimate the generalization performance of the considered model inducted by a given machine learning algorithm, taking into account that:

- A greater number of examples can allow to reduce the error rate but could lead to an overfitting model.
- A lower number of examples can lead to an underfitting model.

The goal of the various cross-validation approaches is therefore to split the original dates by defining: A subset on which the algorithm is trained (training set), a set on which the algorithm is tested (test set) and, if for example the model has parameters to be evaluated, a set to evaluate precisely how to set parameters optimally (validation set).

Because of its simplicity, the most used technique is the holdout approach, that is the random partition of the original dataset into training set, test set and, eventually, validation set.

One of the biggest drawbacks of the hold-out approach is that the estimate of generalization performance strongly depends on the choice of the training and the test set.

Cross-validation k-fold can be seen as an iterative extension of the holdout method. In particular in the k-fold approach, the original $\mathcal{D}$ dataset having N instances is partitioned into k subsets through a random sampling without replacement. Then the learning algorithm is trained on $k-1$ data sets and the remaining i -th set is used as a test set. Finally, to obtain an estimate that does not depend on the resampling of data, the average performance of the models is considered.

The most used variant of the k-fold cross validation are:

- Ten-fold cross-validation, in which $k=10$,
- Leave-one-out cross-validation, in which $k=n$ and so for each iteration the learning algorithm is trained on $N-1$ instances and tested on the remaining one.

Ensemble Learning

As stated in the introduction, the ensemble learning methods were introduced in order to induce a model with better performances or, in other words to build a “strong” learner by combining multiple “weak” or base learners, i.e., learners having an error rate that is slightly lower than the random guessing.

In fact, the theoretical basis shows that the model induced by more weak and independent learners combined by some suitable function (for example majority voting), can lead to an error rate that is lower than the error of each single base-learner (Caritat and de Concorcet, 1785).

Without going into detail, the concept of independence between learners can be made explicit by asking for the base-learners’ errors not to be correlated or, in other terms, that different base-learners tend to produce different errors. Unfortunately, there is a trade-off between diversity and accuracy and a key role for this problem is played by the choice of an suitable combining function (Kuncheva, 2004; Valentini and Masulli, 2002).

In summary, two are the main step that have to be considered in order to build a good ensemble:

- Build the ensemble in such a way that base-learners will be diverse and accurate,
 - Combining each base-learner result in a suitable way that can improve accuracy, i.e., lowering bias and/or variance.
- Diversity can be promoted in an implicit way, for example by training the same learning algorithm on different subset of the training set (variation in data), or explicitly choosing different learning algorithm (variation among learners) (Brazdil et al., 2008). Moreover, there are multiple choices for the combining function. Given N learners, i an instance, d_j the output of the j -th learner, $\mathcal{L}$ a class label set and indicating with d_{ens} the ensemble learner’s output and with $d_{j,c}(i) = \chi_{\text{mathcall}}(d_j(i) = c)$, with $c \in \text{mathcall}$, some examples for combining the base learners’ output are listed below:
- Combining function for class labels:
 - Majority voting: $d_{ens}(i) = \underset{c}{\operatorname{argmax}} \sum_j 1^N d_{j,c}(i)$
 - Borda count Van Erp and Schomaker (2000)
 - Combining function for numerical output:
 - Mean rule: $d_{ens}(i) = \frac{1}{N} \sum_j 1^N d_j(i)$
 - Weighted average $d_{ens}(i) = \frac{1}{N} \sum_j 1^N w_j d_j(i)$, for w_j be such that $\sum_{j=1}^N w_j = 1$
 - Minimum rule $d_{ens}(i) = \min_{j \in [1 \dots N]} d_j(i)$
 - Maximum rule $d_{ens}(i) = \max_{j \in [1 \dots N]} d_j(i)$
 - Median rule $d_{ens}(i) = \min_{j \in [1 \dots N]} d_j(i)$
 - Product rule $d_{ens}(i) = \frac{1}{N} \prod_j 1^N w_j d_j(i)$

The Stacking Algorithm

Compared to Bagging and Boosting, in Stacking two are the major differences:

- While Bagging and Boosting harness diversity with variation in data, Stacking exploit diversity among learners,
 - Instead of making use of one among the combining function listed in the previous Section, in Stacking a new learner is applied to a meta-dataset containing the base-learners output.
- In fact Bagging and Boosting, despite their simplicity, effectiveness and popularity, have as a weak point to subtract interpretability to the ensemble model, in the sense that these approach don’t allow to explicitly know which base-learners is likely to be accurate in which part of the feature space. For that reason in stacking two learning level are foreseen:
- At a first level the base-learners are trained and tested on the original dataset with a cross validation approach,
 - At a second level a new learning algorithm (meta-learner) is trained on a new meta-dataset.

More in details, the stacking process is shown in Fig. 1: At first n learning algorithms ($L_1, \dots, L_n$) are considered and trained on a partition of the dataset $\mathcal{D}$ obtained by applying cross validation to the original dataset. After this training phase, a series of models ($M_1, \dots, M_n$) are produced and tested with the remaining partition of the original dataset. Then, a new meta-dataset $\mathcal{D}_{\text{meta}}$ is built by adding or replacing each base-learner’s prediction for each instance i in the set used from testing the base-learners.

Fig. 1 The Stacking algorithm.

As in cross validation, the advantage of building the meta-dataset from the test set is that this new dataset reflects in some way the real performances of each base-learner, excluding the possibility of memorizing the dataset.

The “meta-dataset” become the training set for the meta-learner algorithm in order to build a new meta-model with the aim of mapping the prediction of each base-learner to a final output, for example a class label in a classification problem.

Then, for each new instance i , all the base-learners’ induced models make a prediction building the corresponding instance i_{meta} in the meta-dataset $\mathcal{D}_{meta}$ and then is sent to the meta-model in order to produce the final prediction for i .

Unlike a fixed rule, like majority voting, the presence of a meta-learner has the advantage of adding flexibility and lowering the bias, with the risk, however, of increasing variance. Another disadvantage is to increase the complexity in terms of time and need a larger dataset for a further training phase.

However, the main weakness of this technique is that there is not an accepted best way for doing stacking, because it’s not suitable for theoretical analysis. (Witten *et al.*, 2016). One of the major issue is what can be the most suitable algorithm used to construct the meta-model. Good results have been given by using linear meta-models (Wolpert, 1992). Stacking were also applied to linear regression problem (Breiman, 1996), while in (Ting and Witten, 1997), was shown that an improvement in performance is achieved by using the class probabilities rather than the individual outputs for each base-learner and a multi-response least-squares algorithm as meta-learner algorithm.

Multiple Learners Combination: Cascading

Chiara Zucco, University “Magna Graecia” of Catanzaro, Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

With the development of high-throughput experimental technologies, in the last decades the omics sciences have seen a huge increase of data in biological databases, both in terms of numbers and in terms of complexity, to the point of considering bioinformatic data as “big data”. Machine learning and Data Mining approach have proved to play a key role in analyzing these vast amount of data and are widely used, especially for prediction and classification tasks.

In order to improve the prediction performances, accurate models are needed. The No free lunch Theorems (Wolpert and Macready, 1997) state that in free domains context, it doesn't exist an algorithm always outperforming another learning algorithm, even if we consider the random guessing algorithm as basis for comparison.

A possible solution that arise as an alternative option for looking for the algorithm that, in that context, induces the “optimal” model, is the idea that a combination of multiple “weak” learners, inducing more simple model, could approximate this optimal model allowing to reach better performances than a single weak or base learner. This kind of approaches are addressed as ensemble learning (Kuncheva, 2004; Polikar, 2012; Alpaydin, 2014; Valentini and Masulli, 2002).

In this article the Cascading process is presented, developed by Alpaydin and Kaynak (1998). As a first application, cascading was used for the handwriting digit recognition and compared to other ensemble approaches with positive results, see Alpaydin *et al.* (2000). Moreover, one of the most popular application of cascading can be found in the Viola-Jones algorithm for a real-time face recognition framework. In this work, visual features are extracted thanks to a particular image representation, called integral image, then features were selected using another ensemble learning approach discussed in a previous article, that is the Adaptive Boosting algorithm, or Adaboost. Adaboost algorithm is also used in order to train classifiers that are combined using the cascading approach.

A significant example of how cascading can be used for the construction of a gene expression data classification system related to lung cancer is presented by Iakovidis *et al.* (2004). Given N possible class labels, the system is built by combining in a cascade fashion $N - 1$ SVM classifiers. The system was then applied to a six classes classification problem of lung cancer data. Results shows an estimated accuracy of 98.5%.

Background and Fundamentals

Before discussing the details of the cascading approach in combining multiple learner, in this Section the basis of constructing an ensemble of machine learning algorithms will be summarised.

Ensemble Learning

As stated in the Introduction, one of the major implications of the No Free Lunch theorems is that, given two learning algorithms L_1 and L_2 , there are (on average) as many situations in which L_1 induced model fits data better than L_2 model as there are situations in which L_2 model fits data better than L_1 and this is also true if it's included the random guessing algorithm. In other words, for each algorithm there are many situations in which it induces a model that describes well observed data, and many other cases in which the model induced by that same algorithm fails.

Ensemble learning methods were introduced as a way to induce a model with better performances or, in other words, to build a “strong” learner by combining multiple “weak” or base learners, i.e., learners having an error rate that is slightly lower than the random guessing.

The basic principle of ensemble methods found many analogies in real life, let's think for examples to democratic processes. It's not a case that the theoretical basis for ensemble learning models can be found in a political science Theorem, known as the “Condorcet's Jury's Theorem”, showing that the model induced by more weak and independent learners combined by some suitable function (for example majority voting), can lead to an error rate that is lower than the error of each single base-learner, see Caritat and de Concorcet (1785).

Without going into detail, the concept of independence between learners can be made explicit by asking that different base-learners tend to produce errors on different instances (errors have to be uncorrelated). Unfortunately, the more the more learners are accurate, the less they are diverse, in the sense that the correlation between errors increases. In order to find a trade-off between diversity and accuracy, the choice of a suitable combining function plays a key role (Kuncheva, 2004; Valentini and Masulli, 2002).

The main issues to be considered in order to build a good ensemble are:

- To build the ensemble by choosing sufficiently accurate base learners and by encouraging diversity among base-learners;
- Combining each base-learner result in a suitable way that can improve accuracy, i.e., lowering bias and/or variance.

Diversity can be promoted both in an implicit way and in an explicit way. For example in Bagging algorithms the same learning algorithm is trained in parallel on different subsets of the training set and the diversity of the base learners is achieved by applying a variation in training data. Also in Boosting diversity is achieved by using the same learning algorithm on a different subset of the training data, but in this case the base-learners are trained in a sequence fashion on a subset containing also the instances misclassified by the previous learners. On the contrary, in stacking the ensemble is built by explicitly choosing different learning algorithms and training them in parallel on the same training set (for further details see Brazdil et al., 2008).

Moreover, there are multiple choices for the combining function. Let consider N learners, an instance i and the output d_j of the j -th learner. Furthermore, indicating with $\mathcal{L}$ a set of class labels, with d_{ens} the output of the ensemble classifier and with $d_{j,c}(i) = \chi_{\text{mathcall}}(d_j(i) = c)$ the characteristic function for $c \in \text{mathcall}$, some examples for combining the base learners' output are listed below:

- Combining function for class labels:
 - Majority voting: $d_{ens}(i) = \text{argmax} \sum_{j=1}^N d_{j,c}(i)$
 - Borda count (Van Erp and Schomaker, 2000)
- Combining function for numerical output:
 - Mean rule: $d_{ens}(i) = \frac{1}{N} \sum_{j=1}^N d_j(i)$
 - Weighted average $d_{ens}(i) = \frac{1}{N} \sum_{j=1}^N w_j d_j(i)$, for w_j be such that $\sum_{j=1}^N w_j = 1$
 - Minimum rule $d_{ens}(i) = \min_{j \in [1 \dots N]} d_j(i)$
 - Maximum rule $d_{ens}(i) = \max_{j \in [1 \dots N]} d_j(i)$
 - Median rule $d_{ens}(i) = \text{median}_{j \in [1 \dots N]} d_j(i)$
 - Product rule $d_{ens}(i) = \frac{1}{N} \prod_{j=1}^N w_j d_j(i)$

It can be proven that majority voting can lower the variance of the model without having strong effects on bias and for this reason is used as combining function in Bagging, because Bagging is more effective when using as learning algorithm an instable one. The weak point of these combining functions is that the resulting ensemble model has a loss in interpretability, because the information about which learner seems to be more accurate on a given part of the considered feature space is lost. Instead, in Stacking the combining function is a trainable arbiter, i.e., a new learning algorithm called meta-learner.

Fig. 1 The Cascading scheme for combining n Learners' predictions.

The Cascading Algorithm

Cascading is an ensemble method that uses different learning algorithms by combining them in sequence. In particular, in fact, in this case the base learners are ordered in an increasing way according to their spatial or temporal complexity or even on the basis of the cost of the representation used by the algorithm. Let's consider a classification problem. Unlike majority voting, for which each base-classifier's output is considered, in cascading, the "simpler" classifiers are those that are used to classify most of the instances, while more complex classifiers will be only used when the simplest ones do not give an output with certain confidence. In this sense, Cascading can be seen as a multistage method.

In the previous section we saw how Bagging, Boosting and Stacking mainly focus on the output of individual base-learners, which are then combined in some way. The main difference in Cascading is that, instead of considering only the base-learner's output, to each learner $\mathcal{L}_j$ is associated a confidence function ω_j and, as long as the base-learner's confidence on a given instance x is lower than a set threshold, then a following base-learner is used.

More in details, let's consider the initial dataset partitioned through a cross validation approach in a Training set T and in a Validation set V , a sequence $L_1 \dots L_n$ of classifiers and a sequence $0 < \theta_1 < \theta_n < 1$ of threshold values.

In the first step of cascading, the first classifier L_1 of the sequence is trained on the training set T and by considering on T a uniform distribution of the instances, as in the case of boosting. For the classifier L_1 and, more in general, for every classifier L_j it is possible to determine the posterior probability that the instance x is assigned to the class $c_k \in \{c_1 \dots c_m\}$, i.e.,

$$\rho_{k,j} = \mathcal{P}(c_k | x, L_j)$$

and it is also possible to assign a confidence function $\omega_j(x)$ of the classifier that is defined as

$$\omega_j(x) = \max_{c_k \in \{c_1 \dots c_m\}} \mathcal{P}(c_k | x, L_j) = \max_{c_k \in \{c_1 \dots c_m\}} \rho_{k,j}$$

If the x instance is predicted by the classifier L_1 with a confidence $\omega_1(x) > \theta_1$, then the output of L_1 will be accepted as the output of the ensemble L_{ens} , otherwise the output of the L_1 classifier will be rejected and then the instance must be classified by one of the following classifiers.

Technically, the subsequent classifiers L_{j+1} will be trained on the same dataset T having however a different distribution that depends on the confidence function ω_j of the previous classifier. In general the output of the ensemble for that instance will be given by

$$P_{ens}(x) = \arg \max_{c_k \in \{c_1 \dots c_m\}} \rho_{k,j}(x), \text{ if } \omega_j(x) > \theta_j \text{ and } \forall i < j, \omega_i(x) < \theta_i.$$

In **Fig. 1** is shown the process just described.

Cross-Validation

Daniel Berrar, Tokyo Institute of Technology, Tokyo, Japan

© 2019 Elsevier Inc. All rights reserved.

Introduction

Cross-validation is a data resampling method to assess the generalization ability of predictive models and to prevent overfitting (Hastie *et al.*, 2008; Duda *et al.*, 2001). Like the bootstrap (Efron and Tibshirani, 1993), cross-validation belongs to the family of Monte Carlo methods.

Consider a data set D , which consists of n labeled instances (or cases), x_i , $i = 1 \dots n$. Each case is described by a set of attributes (or features). We assume that each case x_i belongs to exactly one class y_i . A typical example from bioinformatics is a gene expression data set based on DNA microarray data, where each case represents one labeled tumor sample described by a gene expression profile. One of the common challenges concerns the development of a classifier that can reliably predict the class of new, unseen tumor samples based on their expression profiles (Berrar *et al.*, 2007). Conceptually, a predictive model, $f(\cdot)$, is a rule for assigning a class label to a case based on a data set D , i.e., $f(x_i, D) = \hat{y}_i$, where $\hat{y}_i$ is the predicted class label for case x_i . In machine learning, the construction of such a model is denoted as *supervised learning*.

A central question in supervised learning concerns the accuracy of the resulting model. Here, a key problem is *overfitting* (Berrar and Dubitzky, 2013). It is very easy to build a model that is perfectly adapted to the data set at hand but then unable to generalize well to new, unseen data. For example, consider a univariate regression problem where we wish to predict the dependent variable y from the independent variable x based on n observations, (x_i, y_i) , with $i = 1 \dots n$. We could use a polynomial of degree $n - 1$ to interpolate these points perfectly and then use the resulting curve to extrapolate the value y_{i+1} for a new case, x_{i+1} . However, this curve is very likely to be *overfitted* to the data at hand – not only does it reflect the relation between the dependent and independent variable, but it has also modeled the inherent noise in the data set. On the other hand, a simpler model, such as a least squares line, is less affected by the inherent noise, but it may not capture well the relation between the variables, either. Such a model is said to be *underfitted*. Neither the overfitted nor the underfitted model are expected to generalize well, and a major challenge is to find the right balance between over- and underfitting.

How can we assess the generalization ability of a model? Ideally, we would evaluate the model using new data that originate from the same population as the data that we used to build the model (Simon, 2003). In practice, new independent validation studies are often not feasible, though. Also, before we invest time and other resources for an external validation, it is advisable to estimate the predictive performance first. This is usually done by *data resampling methods*, such as cross-validation. This article describes the major subtypes of cross-validation and their related resampling methods.

Basic Concepts and Notation

The data set that is available to build and evaluate a predictive model is referred to as the *learning set*, D_{learn} . This data set is assumed to be a sample from a population of interest. Random subsampling methods are used to generate training set(s), D_{train} , and test set(s), D_{test} , from the learning set. The model is then built (or trained) using the training set(s) and tested on the test set(s). The various random subsampling methods differ with respect to how the training and test sets are generated.

Note that the term “training” implies that we apply the learning algorithm to a subset of the data. The resulting model, $\hat{f}(x, D_{\text{train}})$, is only an estimate of the final model that results from applying the same learning function to the entire learning set, $f(x, D_{\text{learn}})$. Model evaluation based on repeated subsampling means that a learning function is applied to several data subsets, and the resulting models, $\hat{f}_j$, are subsequently evaluated on other subsets (i.e., the test sets or validation sets), which were not used during training. The average of the performance that the models $\hat{f}_j$ achieve on these subsets is an estimate of the performance of the final model, $f(x, D_{\text{learn}})$.

Let us assume that with each case, exactly one target label y_i is associated. In the case of classification, y_i is a discrete class label. A classifier is a special case of a predictive model that assigns a discrete class label to a case. In regression tasks, the target is usually a real value, $y_i \in \mathbb{R}$. A predictive model $f(\cdot)$ estimates the target y_i of the case x_i as $f(x_i) = \hat{y}_i$. A *loss function*, $\mathcal{L}(y_i, \hat{y}_i)$, quantifies the estimation error. For example, using the 0-1 loss function in a classification task, the loss is 1 if $y_i \neq \hat{y}_i$ and 0 otherwise. With the loss function, we can now calculate two different errors, (1) the *training error* and (2) the *test error*. The training error (or resubstitution error) tells us something about the adaptation to the training set(s), whereas the test error is an estimate of the true prediction error. This estimate quantifies the generalization ability of the model. Note that the training error tends to underestimate the true prediction error, since the same data that were used to train the model are reused to evaluate the model.

Single Hold-Out Random Subsampling

Among the various data resampling strategies, one of the simplest ones is the *single hold-out method*, which randomly samples some cases from the learning set for the test set, while the remaining cases constitute the training set. Often, the test set contains about

10%–30% of the available cases, and the training set contains about 90%–70% of the cases. If the learning set is sufficiently large, and consequently, if both the training and test sets are large, then the observed test error can be a reliable estimate of the true error of the model for new, unseen cases.

***k*-fold Random Subsampling**

In *k*-fold random subsampling, the single hold-out method is repeated k times, so that k pairs of $D_{\text{train},j}$ and $D_{\text{test},j}$, $j=1\dots k$, are generated. The learning function is applied to each training set, and the resulting model is then applied to the corresponding test set. The performance is estimated as the average over all k test sets. Note that any pair of training and test set is disjoint, i.e., the sets do not have any cases in common, $D_{\text{train},j} \cap D_{\text{test},j} = \emptyset$. However, any given two training sets or two test sets may of course overlap.

***k*-fold Cross-Validation**

Cross-validation is similar to the repeated random subsampling method, but the sampling is done in such a way that no two test sets overlap. In *k*-fold cross-validation, the available learning set is partitioned into k disjoint subsets of approximately equal size. Here, *fold* refers to the number of resulting subsets. This partitioning is performed by randomly sampling cases from the learning set *without* replacement. The model is trained using $k-1$ subsets, which, together, represent the training set. Then, the model is applied to the remaining subset, which is denoted as the *validation set*, and the performance is measured. This procedure is repeated until each of the k subsets has served as validation set. The average of the k performance measurements on the k validation sets is the *cross-validated performance*. Fig. 1 illustrates this process for $k=10$, i.e., 10-fold cross-validation. In the first fold, the first subset serves as validation set $D_{\text{val},1}$ and the remaining nine subsets serve as training set $D_{\text{train},1}$. In the second fold, the second subset is the validation set and the remaining subsets are the training set, and so on.

The cross-validated accuracy, for example, is the average of all ten accuracies achieved on the validation sets. More generally, let $\hat{f}_{-k}$ denote the model that was trained on all but the k th subset of the learning set. The value $\hat{y}_i = \hat{f}_{-k}(x_i)$ is the predicted or estimated value for the real class label, y_i , of case x_i , which is an element of the k th subset. The cross-validated estimate of the prediction error, $\hat{e}_{\text{cv}}$, is then given as

$$\hat{e}_{\text{cv}} = \frac{1}{n} \sum_{i=1}^n \mathcal{L}(y_i, \hat{f}_{-k}(x_i)) \quad (1)$$

Cross-validation often involves *stratified* random sampling, which means that the sampling is performed in such a way that the class proportions in the individual subsets reflect the proportions in the learning set. For example, suppose that the learning set contains $n=100$ cases of two classes, the positive and the negative class, with $n_+=80$ and $n_-=20$. If random sampling is done without stratification, then it is quite possible that some validation sets contain only positive cases (or only negative cases). With stratification, however, each validation set in 10-fold cross-validation is guaranteed to contain about eight positive cases and two negative cases, thereby reflecting the class ratio in the learning set. The underlying rationale for stratified sampling is the following. The sample proportion is an unbiased estimate of the population proportion. The learning set represents a sample from the population of interest, so the class ratio in the learning set is the best estimate for the class ratio in the population. To avoid a biased evaluation, data subsets that are used for evaluating the model should therefore also reflect this class ratio. For real-world data sets, Kohavi recommends stratified 10-fold cross-validation (Kohavi, 1995).

To reduce the variance of the estimated performance measure, cross-validation is sometimes repeated with different k -fold subsets (*r times repeated k-fold cross-validation*). However, Molinaro et al. (2005) showed that such repetitions reduce the variance only slightly.

For the comparison of two different classifiers in cross-validation, the variance-corrected *t*-test was proposed (Nadeau and Bengio, 2003; Bouckaert and Frank, 2004). Note that the training sets in the different cross-validation folds overlap, which violates

Fig. 1 10-fold cross-validation. The data set is randomly split into ten disjoint subsets, each containing (approximately) 10% of the data. The model is trained on the training set and then applied to the validation set.

the independence assumption of the standard t -test and leads to an underestimation of the variance. The variance-corrected t -statistic is

$$T = \frac{\frac{1}{kr} \sum_{i=1}^k \sum_{j=1}^r (a_{ij} - b_{ij})}{\sqrt{\left(\frac{1}{kr} + \frac{n_2}{n_1}\right) s^2}} \sim t_{kr-1} \quad (2)$$

This statistic follows approximately Student's t distribution with $k \cdot r - 1$ degrees of freedom. Here, a_{ij} and b_{ij} denote the performances achieved by two competing classifiers, A and B , respectively, in the j th repetition of the i th cross-validation fold; s^2 is the variance; n_2 is the number of cases in one validation set, and n_1 is the number of cases in the corresponding training set. This test should be used carefully, though; by increasing r , even a tiny difference in performance can be made significant, which is misleading because essentially the same data are analyzed over and over again (Berrar, 2017).

Leave-One-Out Cross-Validation

For $k=n$, we obtain a special case of k -fold cross-validation, called *leave-one-out cross-validation* (LOOCV). Here, each individual case serves, in turn, as hold-out case for the validation set. Thus, the first validation set contains only the first case, x_1 , the second validation set contains only the second case, x_2 , and so on. This procedure is illustrated in Fig. 2 for a data set consisting of $n=25$ cases.

The test error in LOOCV is approximately an unbiased estimate of the true prediction error, but it has a high variance, since the n training sets are practically the same, as two different training sets differ only with respect to one case (Hastie et al., 2008). The computational cost of LOOCV can also be very high for large n , particularly if feature selection has to be performed.

Jackknife

Leave-one-out cross-validation is very similar to a related method, called the *jackknife*. Essentially, these two methods differ with respect to their goal. Leave-one-out cross-validation is used to estimate the generalization ability of a predictive model. By contrast, the jackknife is used to estimate the bias or variance of a statistic, $\hat{\theta}$ (Efron and Stein, 1981). Note that the available data set is only a sample from the population of interest, so $\hat{\theta}$ is only an estimate of the true parameter, θ . The jackknife involves the following steps (Duda et al., 2001).

- (1) Calculate the sample statistic $\hat{\theta}$ as a function of the available cases $x_1, x_2, \dots, x_n$, i.e., $\hat{\theta} = t(x_1, x_2, \dots, x_n)$, where $t(\cdot)$ is a statistical function.
- (2) For all $i=1..n$, omit the i th case and apply the same statistical function $t(\cdot)$ to the remaining $n-1$ cases and obtain $\hat{\theta}_i = t(x_1, x_2, x_{i-1}, x_{i+1}, \dots, x_n)$. (NB: the index i means that the i th case is *not* used.)
- (3) The jackknife estimate of the statistic $\hat{\theta}$ is the average of all $\hat{\theta}_i$, i.e., $\bar{\hat{\theta}} = \frac{1}{n} \sum_{i=1}^n \hat{\theta}_i$.

The jackknife estimates of bias and variance of $\hat{\theta}$ are

$$\text{bias}(\hat{\theta}) = (n-1)(\bar{\hat{\theta}} - \hat{\theta}) \quad (3)$$

$$\text{Var}(\hat{\theta}) = \frac{n-1}{n} \sum_{i=1}^n (\hat{\theta}_i - \bar{\hat{\theta}})^2 \quad (4)$$

Fig. 2 Leave-one-out cross-validation, illustrated on a data set containing $n=25$ cases. In turn, each case serves as single hold-out test case. The model is built using the remaining $n-1$ cases.

Discussion

Cross-validation is one of the most widely used data resampling methods to assess the generalization ability of a predictive model and to prevent overfitting. To build the final model for the prediction of real future cases, the learning function (or learning algorithm) f is usually applied to the entire learning set. This final model cannot be cross-validated. The purpose of cross-validation in the model building phase is to provide an estimate for the performance of this final model on new data.

Feature selection is generally an integral part of the model building process. Here, it is crucial that predictive features are selected using only the training set, not the entire learning set; otherwise, the estimate of the prediction error can be highly biased (Ambroise and McLachlan, 2002; Simon, 2007). Suppose that predictive features are selected based on the entire learning set first, and then the learning set is partitioned into validation sets and training sets. This means that information from the validation sets was used for the selection of predictive features. But the data in the validation sets serve only to evaluate the model – we are not allowed to use these data in any other way; otherwise, the information leak would cause a downward bias of the estimate, which means that it underestimates the true prediction error.

Cross-validation is frequently used to tune model parameters, for example, the optimal number of nearest neighbors in a k -nearest neighbor classifier. Here, cross-validation is applied multiple times for different values of the tuning parameter, and the parameter that minimizes the cross-validated error is then used to build the final model. Thereby, cross-validation addresses the problem of overfitting.

Which data resampling method should be used in practice? Molinaro *et al.* (2005) compared various data resampling methods for high-dimensional data sets, which are common in bioinformatics. Their findings suggest that LOOCV, 10-fold cross-validation, and the .632+ bootstrap have the smallest bias. It is not clear, however, which value of k should be chosen for k -fold cross-validation. A sensible choice is probably $k=10$, as the estimate of prediction error is almost unbiased in 10-fold cross-validation (Simon, 2007). Isaksson *et al.* (2008), however, caution that cross-validated performance measures are unreliable for small-sample data sets and recommend that the true classification error be estimated using Bayesian intervals and a single hold-out test set.

Closing Remarks

Cross-validation is one of the most widely used data resampling methods to estimate the true prediction error of models and to tune model parameters. Ten-fold stratified cross-validation is often applied in practice. Practitioners should keep in mind, however, that data resampling is no panacea for fully independent validation studies involving new data.

Performance Measures for Binary Classification

Daniel Berrar, Tokyo Institute of Technology, Tokyo, Japan

© 2019 Elsevier Inc. All rights reserved.

Introduction

Classification problems can be categorized into (1) binary, (2) multiclass, and (3) multilabel tasks. In binary classification tasks, only two classes are considered, which are commonly referred to as the *positive* and *negative* class; for example, healthy vs. diseased, underexpressed vs. overexpressed, smoker vs. non-smoker, etc. By contrast, multiclass tasks include more than just two classes. Some of the measures for binary classification tasks can be easily extended to multiclass problems (Baldi et al., 2000; Ferri et al., 2009). “Single-label” means that an instance (or case) belongs to only one class, whereas “multi-label” means that an instance can simultaneously belong to more than just one class. This article focuses on performance measures for single-label, binary classification tasks, with the goal to provide an easily accessible introduction to the most commonly used quantitative measures and how they are related. Using a simplified example, we illustrate how to calculate these measures and give some general recommendations regarding their use.

In this article, the term “predictive model” should be understood to refer to not only fully specified models from machine learning; instead, the term also encompasses medical diagnostic tests, for example, a blood sugar test for diabetes.

We will begin with some basic notations. Let a data set D contain n instances (or cases) $\mathbf{x}_i$, $i = 1 \dots n$, and let each instance be described by k attributes (or features or covariates). We assume that each instance belongs to exactly one class y_i , with $y \in \{0, 1\}$, where 1 denotes the positive class and 0 denotes the negative class. A *scoring classifier* is a mapping $C: X \rightarrow \mathbb{R}$ that produces a class membership score for each instance, for example, a conditional probability $P(y = 1 | X = \mathbf{x}_i)$. This class membership score expresses the degree of class membership of that instance in the positive class. Here, we will assume that the scores are scaled from 0 to 1 and that they can be interpreted as estimated class posterior probabilities, $C(\mathbf{x}_i) = p_i = P(y = 1 | X = \mathbf{x}_i)$.

As D contains only positive and negative examples, the scoring classifier can either be used as a *ranker* or as a *crisp classifier*. A ranker uses the ordinal scores to order the instances from the most to the least likely to be positive. The ranker can be turned into a crisp classifier by setting a classification threshold t on the score: if $p_i > t$, then the predicted class label is $\hat{y} = 1$; otherwise, $\hat{y} = 0$.

The underlying concept of performance metrics are *scoring rules*, which assess the quality of probabilistic predictions (Buja et al., 2005; Gneiting and Raftery, 2007; Witkowski et al., 2017). Let a model be presented with an instance $\mathbf{x}_i$, which belongs to either the positive or negative class, $y \in \{0, 1\}$. Let the model's *probabilistic belief* be the same as the true probability $p \in [0, 1]$ that the class of $\mathbf{x}_i$ is $y = 1$. The model outputs the *belief report* $q \in [0, 1]$. A scoring rule $R(y, q) \in \mathbb{R}$ assigns a reward based on the reported q and the real class y . A scoring rule is called *proper* if the model maximizes the expected reward by truthfully reporting its belief p . A scoring rule is called *strictly proper* if the reported belief is the only report that maximizes the expected reward. For example, consider the quadratic scoring rule $R(y, q) = 1 - (y - q)^2$. The (true) probability that the instance $\mathbf{x}_i$ belongs to class 1 is p , and the (true) probability that it belongs to class 0 is $(1 - p)$. The expected reward is then $E(R) = [1 - (1 - q)^2]p + [1 - (0 - q)^2](1 - p) = 1 - q^2 + 2pq - p$. Setting the first derivative with respect to q to zero gives $\frac{\partial R}{\partial q} = 2p - 2q = 0$ or $q = p$. As the second derivative, $\frac{\partial^2 R}{\partial q^2} = -2$, is negative, the reward is indeed (uniquely) maximized if $q = p$. Therefore, the model is incentivized to report the true probability, p . The quadratic scoring rule is a strictly proper scoring rule and underlies various performance measures, for example, the Brier score (Definition 18).

As described in (Ferri et al., 2009), the different performance measures can be categorized into three broad families:

1. Performance measures based on a single classification threshold;
 - (a) Elementary performance measures;
 - (b) Composite performance measures;
2. Performance measures based on a probabilistic interpretation of error;
3. Ranking measures.

We will illustrate the performance measures using a contrived example (Fig. 1). Here, ten cases are described by two features, i.e., their x - and y -coordinates; five cases (#3, #6, #7, #9, and #10) belong to the positive class (represented by circles), while the five remaining cases (#1, #2, #4, #5, and #8) belong to the negative class (represented by squares). The classification task is to find a decision boundary, so that cases falling on one side are classified as members of the positive class, while cases falling on the opposite side are classified as members of the negative class.

In Fig. 1, the decision boundary is represented by the solid vertical line. Note that this line is certainly not the optimal decision boundary for this classification problem; nonetheless, it can be used to discern the two classes: the more a case is located to the right of the boundary, the more likely it is a member of the positive class, and vice versa. Case #6 lies exactly on the boundary, so it is reasonable to assign a class membership score of 0.5, with the probabilistic interpretation that the case is equally likely to belong to the positive or negative class. To quantify the degree of class membership of the other cases, we calculate the distance between them and the boundary. For example, the distance between case #8 and the boundary is 0.25, which leads to a score of

Fig. 1 Simplified example. Ten instances of two classes (circles: positive class; squares: negative class) are classified based on a decision boundary (solid black line). Instances to the right of the boundary are predicted as positives, while instances to the left are predicted as negatives. The distance to the boundary is used as class membership score.

	Case	Class	Score	TPR	FPR	Prec	Cum.class	Lift
t_1	10	1	0.95	1/5	0	1	1	2
t_2	9	1	0.8	2/5	0	1	2	2
t_3	8	0	0.75	2/5	1/5	2/3	2	4/3
t_4	7	1	0.6	3/5	1/5	3/4	3	3/2
t_5	6	1	0.5	4/5	1/5	4/5	4	8/5
•	5	0	0.45	4/5	2/5	4/6	4	4/3
•	4	0	0.3	4/5	3/5	4/7	4	8/7
•	3	1	0.25	5/5	3/5	5/8	5	5/4
	2	0	0.2	5/5	4/5	5/9	5	10/9
t_{11}	1	0	0.1	5/5	5/5	5/10	5	10/10

Fig. 2 Ranking table for the introductory example (Fig. 1), with performance measures resulting from 11 different classification thresholds $t_1 \dots t_{11}$. Each case *above* the threshold is classified as a positive. It is assumed that classification thresholds always fall between actual scores. TPR, true positive rate = recall = sensitivity; FPR, false positive rate = $1 - \text{specificity}$; Prec, precision = positive predictive value; Cum.class, cumulative class count.

$0.5 + 0.25 = 0.75$. Case #3 lies on the opposite side of the boundary but has the same distance, so we use $0.5 - 0.25 = 0.25$ as its membership score for the positive class. Analogously, we can derive the scores for all ten cases and rank them as shown in Fig. 2.

This contrived example is deliberately simplified, and real classification algorithms usually calculate the class membership scores in a more sophisticated way. But the example illustrates the key idea: a model separates positive and negative cases and quantifies their class membership by a score, which can be used to rank the cases from the most likely to be positive to the least likely to be positive.

Note that many performance measures are known under different names. The reason is that the same measures were developed in different fields of science; for example, in epidemiology and medicine, the term “positive predictive value” is widely used, whereas in machine learning and information retrieval, the term “precision” is more common. Similarly, “sensitivity” is commonly used in the context of biomedical tests, whereas “recall” is more common in information retrieval. Mathematically, there is of course no difference between these synonyms.

Performance Measured Based on a Single Classification Threshold

Consider Fig. 2. Here, all cases *above* threshold t_5 (dotted line) are classified as positive cases, while all cases *below* the line are classified as negative cases. Several elementary performance measures can now be derived from such a single classification threshold. The classification results are often represented in a 2×2 table or *confusion matrix*, as shown in Fig. 3(a), with the elementary concepts of true positives (TP, a case is really a positive case and predicted as positive); false positive (FP, a case is really a negative case but predicted as a positive); false negative (FN, a case is really a positive case but predicted as negative); and true negative (TN, a case is really a negative case and predicted as negative). The number of false positives is also known as Type I error,

(a)		Real		
		Positive class	Negative class	
Predicted	Positive class	TP	FP (Type I error)	TP + FP
	Negative class	FN (Type II error)	TN	FN + TN
		TP + FN	FP + TN	TP + FP + FN + TN

(b)		Real		
		Positive class	Negative class	
Predicted	Positive class	3	1	4
	Negative class	2	4	6
		5	5	10

Fig. 3 (a) Confusion matrix for a binary classification task. (b) Confusion matrix for Fig. 2.

and the number of false negatives is known as Type II error. The corresponding counts for the introductory example are shown in Fig. 3(b).

Elementary Performance Measures

From the confusion matrix in Fig. 3(a), several elementary performance measures can be derived.

Definition 1: Accuracy.

The *accuracy* is the proportion of correct classifications,

$$\text{accuracy} = \frac{TP + TN}{TP + FP + FN + TN} \quad (1)$$

For the introductory example (Fig. 2), the accuracy is $\frac{3+4}{3+1+2+4} = 0.70$ for the classification threshold t_5 .

Definition 2: Error rate.

The *error rate* is the proportion of incorrect classifications,

$$\text{error rate} = \frac{FP + FN}{TP + FP + FN + TN} \quad (2)$$

For the introductory example (Fig. 2), the error rate is $1 - \text{accuracy} = 0.30$ for the classification threshold t_5 .

Definition 3: Sensitivity or recall or true positive rate.

The *sensitivity* (or *recall* or *true positive rate*, TPR) is the number of correctly predicted positive cases divided by the number of all positive cases,

$$\text{sensitivity} = \frac{TP}{TP + FN} \quad (3)$$

For the introductory example (Fig. 2), the sensitivity is $\frac{3}{5} = 0.60$. The sensitivity can also be stated as a conditional probability, $P(\hat{y} = 1|y = 1)$.

Definition 4: Specificity or true negative rate.

The *specificity* (or *true negative rate*, TNR) is the number of correctly predicted negative cases divided by the number of all negative cases,

$$\text{specificity} = \frac{TN}{FP + TN} \quad (4)$$

For the introductory example (Fig. 2), the specificity is $\frac{4}{5} = 0.80$. The specificity can also be stated as a conditional probability, $P(\hat{y} = 0|y = 0)$.

Definition 5: Precision or positive predictive value.

The *precision* (or *positive predictive value*) is the number of correctly predicted positive cases divided by the number of all cases that are predicted as positive,

$$\text{precision} = \frac{TP}{TP + FP} \quad (5)$$

For the introductory example (Fig. 2), the precision is $\frac{3}{4} = 0.75$. The precision can also be stated as a conditional probability, $P(y = 1|\hat{y} = 1)$.

Definition 6: Negative predictive value.

The *negative predictive value* is the number of correctly predicted negative cases divided by the number of all cases that are predicted as negative,

$$\text{negative predictive value} = \frac{TN}{TN + FN} \quad (6)$$

For the introductory example (Fig. 2), the negative predictive value is $\frac{4}{6} = 0.67$. The negative predictive value can also be stated as a conditional probability, $P(y = 0|\hat{y} = 0)$.

Definition 7: False discovery rate.

The *false discovery rate* (FDR) is the number of false positives divided by the number of cases that are predicted as positive,

$$\text{FDR} = \frac{FP}{FP + TP} \quad (7)$$

For the introductory example (Fig. 2), the false discovery rate is $\frac{1}{4} = 0.25$. The false discovery rate can also be stated as a conditional probability, $P(y = 0|\hat{y} = 1)$.

Composite Performance Measures Derived From Elementary Measures

From the elementary performance measures, several composite measures can be constructed, such as the Youden index, which is defined as follows (Youden, 1950).

Definition 8: Youden index.

The *Youden index* (or Youden's J statistic) is defined as

$$J = \text{sensitivity} + \text{specificity} - 1 \quad (8)$$

Often, the maximum Youden index is reported, i.e., $J_{\max} = \max_t \{\text{sensitivity}(t) + \text{specificity}(t) - 1\}$, where t denotes the classification threshold for which J is maximal (Ruopp et al., 2008). For the introductory example (Fig. 2), the sum of sensitivity and specificity is maximized for t_6 , for which both sensitivity and specificity are 0.8 (see Fig. 5(a)), and $J_{\max} = 0.6$.

Definition 9: Positive likelihood ratio.

The *positive likelihood ratio* (LR_+) is defined as

$$LR_+ = \frac{\text{sensitivity}}{1 - \text{specificity}} = \frac{P(\hat{y} = 1|y = 1)}{P(\hat{y} = 1|y = 0)} \quad (9)$$

For the introductory example (Fig. 2), the positive likelihood ratio is $\frac{3/5}{1-4/5} = 3.0$.

Definition 10: Negative likelihood ratio.

The *negative likelihood ratio* (LR_-) is defined as

$$LR_- = \frac{1 - \text{sensitivity}}{\text{specificity}} = \frac{P(\hat{y} = 0|y = 1)}{P(\hat{y} = 0|y = 0)} \quad (10)$$

For the introductory example (Fig. 2), the negative likelihood ratio is $\frac{1-3/5}{4/5} = 0.5$.

Definition 11: Balanced accuracy.

The *balanced accuracy* (BACC) is the average of sensitivity and specificity,

$$\text{BACC} = \frac{\text{sensitivity} + \text{specificity}}{2} \quad (11)$$

For the introductory example (Fig. 2), the balanced accuracy is $\frac{1}{2}(\frac{3}{5} + \frac{4}{5}) = 0.70$.

Definition 12: F-measure.

The *F-measure* (also known as F_1 -score or simply F -score) is the harmonic mean of precision and recall,

$$F\text{-measure} = 2 \cdot \frac{1}{\frac{1}{\text{precision}} + \frac{1}{\text{recall}}} = 2 \cdot \frac{\text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}} \quad (12)$$

The multiplication by the constant 2 scales the measure to 1 when both precision and recall are 1. For the introductory example (Fig. 2), the F -measure is $2 \cdot \frac{3/4 \cdot 3/5}{3/4 + 3/5} = 0.67$.

Definition 13: F_β -measure.

The F_β -measure is the general form of the F -measure,

$$F_\beta = (1 + \beta^2) \cdot \frac{\text{precision} \cdot \text{recall}}{\beta^2 \text{precision} + \text{recall}} \quad (13)$$

where the positive real constant β allows for an unequal weighting of precision and recall.

Definition 14: G-measure.

The G-measure is the geometric mean of precision and recall,

$$\text{G-measure} = \sqrt{\text{precision} \cdot \text{recall}} \quad (14)$$

For the introductory example (Fig. 2), the G-measure is $\sqrt{3/4 \cdot 3/5} = 0.671$ for the classification threshold t_5 .

Matthews correlation coefficient (Matthews, 1975) is a discretization of the Pearson correlation coefficient (Powers, 2011).

Definition 15: Matthews correlation coefficient.

Matthews correlation coefficient (MCC) is defined as

$$\text{MCC} = \frac{TP \cdot TN - FP \cdot FN}{\sqrt{(TP + FN)(TP + FP)(TN + FP)(TN + FN)}} \quad (15)$$

with $\text{MCC} \in [-1, 1]$, where -1 indicates perfect negative correlation (i.e., the model predicts all negatives as positives, and vice versa), 0 indicates no correlation (i.e., the model predicts randomly), and $+1$ indicates perfect positive correlation (i.e., the model predicts all real positives as positives and all real negatives as negatives).

For the introductory example (Fig. 2), $\text{MCC} = \frac{3 \cdot 4 - 1 \cdot 2}{\sqrt{(3+2)(3+1)(4+1)(4+2)}} = 0.408$. Note that Eq. (15) may lead to the indeterminate form $\frac{0}{0}$, for example, if $TP + FN = 0$, which means that the classifier predicts all cases as instances of the negative class. As the positive class is never predicted, this is most likely an indication that something is wrong with the model. The MCC is suitable for imbalanced data sets (Boughorbel et al., 2017); however, this measure is not easily generalizable to more than two classes (Baldi et al., 2000).

Definition 16: Lift.

The lift measures how much better the predictions by the model, C , are compared to a *baseline* or *null model*. The lift for the positive class is defined as

$$\text{lift}(y = 1) = \frac{P(y = 1 | \hat{y}_C = 1)}{P(\hat{y}_{\text{null}} = 1)} \quad (16)$$

where $P(y = 1 | \hat{y}_C = 1)$ denotes the probability that the case is really a positive, given that the model predicted that it is positive, and $P(\hat{y}_{\text{null}} = 1)$ is the probability that the null model predicts it as a positive.

Commonly, the null model is random guessing, so the probability of predicting a case as a positive is estimated as the proportion of positive cases in the training set, i.e., the prior probability of positive cases (which is also referred to as *prevalence*) (Dubitzky et al., 2001). Put simply, the lift tells us how much better our predictions are when we use our real model, compared to using just random guessing. To illustrate the lift, let us consider again the introductory example (Fig. 3). For the classification threshold t_5 , the model predicts 4 test cases as positives, and 3 of these predictions are correct, hence, $P(y = 1 | \hat{y}_C = 1) = \frac{3}{4}$. Let us assume that the class ratio of positives and negatives is the same in the training set, i.e., half of the cases are positives and the other half are negatives; hence, $P(\hat{y}_{\text{null}} = 1) = \frac{1}{2}$. Therefore, the lift for the positive class is $\frac{3/4}{1/2} = 1.5$. So loosely speaking, we are doing 1.5 times better with the model than with random guessing. This can also be expressed in terms of *gain*: using the model, we expect to predict 3 out of 4 positives correctly, whereas with random guessing, we expect to predict only 2 correctly – hence, we “gain” 1 correct prediction. The lift and gain are usually calculated for all possible classification thresholds and visualized in a *lift chart* and *gain chart*, respectively. These charts are discussed in Section “Ranking Measures”.

Performance Measures Based on a Probabilistic Understanding of Error

Suppose that a model C_1 produces the score $P(y = 1 | \mathbf{x}_-) = 0.9$ for a real negative test case $\mathbf{x}_-$, whereas another model C_2 produces the score $P(y = 1 | \mathbf{x}_-) = 0.8$. Both models misclassify $\mathbf{x}_-$ as a positive case, but which model is making the more serious error? Here, it is useful to consider the deviation of the predicted class posterior probability from the real class label, which is coded as 1 for the positive and 0 for the negative class. Performance measures that take this deviation into account are based on a probabilistic understanding of error.

Definition 17: Mean absolute error.

The *mean absolute error* (MAE) is defined as

$$\text{MAE} = \frac{1}{n} \sum_{i=1}^n |y_i - p_i| \quad (17)$$

where $y_i \in \{0,1\}$ and $p_i = P(y_i = 1 | \mathbf{x}_i) = C(\mathbf{x}_i)$ is the predicted class membership score and n is the number of test cases.

For the introductory example (Fig. 2), the mean absolute error is calculated as $\text{MAE} = \frac{1}{10}(|1 - 0.95| + |1 - 0.80| + |0 - 0.75| + |1 - 0.6| + |1 - 0.5| + |0 - 0.45| + |0 - 0.3| + |1 - 0.25| + |0 - 0.2| + |0 - 0.1|) = 0.370$.

Definition 18: Mean squared error or Brier score.

The *mean squared error* (MSE) or *Brier score* (Brier, 1950) is defined as

$$\text{MSE} = \frac{1}{n} \sum_{i=1}^n (y_i - p_i)^2 \quad (18)$$

where $y_i \in \{0,1\}$ and $p_i = P(y_i = 1 | \mathbf{x}_i) = C(\mathbf{x}_i)$ is the predicted class membership score and n is the number of test cases.

For the introductory example (Fig. 2), $\text{MSE} = \frac{1}{10}[(1 - 0.95)^2 + (1 - 0.80)^2 + (0 - 0.75)^2 + (1 - 0.6)^2 + (1 - 0.5)^2 + (0 - 0.45)^2 + (0 - 0.3)^2 + (1 - 0.25)^2 + (0 - 0.2)^2 + (0 - 0.1)^2] = 0.192$.

Definition 19: Root mean square error.

The *root mean square error* (RMSE) is defined as

$$\text{RMSE} = \sqrt{\frac{1}{n} \sum_{i=1}^n (y_i - p_i)^2} \quad (19)$$

where $y_i \in \{0,1\}$ and $p_i = P(y_i = 1 | \mathbf{x}_i) = C(\mathbf{x}_i)$ is the predicted class membership score and n is the number of test cases.

For the introductory example (Fig. 2), $\text{RMSE} = \sqrt{0.192} = 0.438$.

The *logarithmic loss* (logloss) or *cross-entropy* is an information-theoretic measure. Note that the Kullback-Leibler divergence is the cross-entropy minus the entropy.

Definition 20: Logloss or cross-entropy.

Let a model C produce scores $p_i \in]0, 1[$ for n instances $\mathbf{x}_i$, e.g., class posterior probabilities $C(\mathbf{x}_i) = P(y_i = 1 | \mathbf{x}_i) = p_i$. The *logarithmic loss* (logloss) or *cross-entropy* is defined as

$$\text{logloss} = -\frac{1}{n} \sum_{i=1}^n y_i \log_2 p_i + (1 - y_i) \log_2 (1 - p_i) \quad (20)$$

where $y_i \in \{0,1\}$, and $p_i \neq 1$ and $p_i \neq 0$.

The smaller the logloss, the better the predictions. If $p_i = 0$ or $p_i = 1$, then the logloss is not defined because of $\log_2 0$; therefore, $\log_2 p_i$ is then calculated as $\log_2(\max\{p_i, \varepsilon\})$, where ε is a small positive constant. Ferri *et al.* suggest $\varepsilon = 10^{-5}$ (Ferri *et al.*, 2009). For the introductory example (Fig. 2), the logloss is calculated as follows.

$$\begin{aligned} \text{logloss} &= -\frac{1}{10} [1 \cdot \log_2(0.95) + (1 - 1) \cdot \log_2(1 - 0.95) \\ &\quad + 1 \cdot \log_2(0.8) + (1 - 1) \cdot \log_2(1 - 0.8) \\ &\quad + 0 \cdot \log_2(0.75) + (1 - 0) \cdot \log_2(1 - 0.75) \\ &\quad + 1 \cdot \log_2(0.6) + (1 - 1) \cdot \log_2(1 - 0.6) \\ &\quad + 1 \cdot \log_2(0.5) + (1 - 1) \cdot \log_2(1 - 0.5) \\ &\quad + 0 \cdot \log_2(0.45) + (1 - 0) \cdot \log_2(1 - 0.45) \\ &\quad + 0 \cdot \log_2(0.3) + (1 - 0) \cdot \log_2(1 - 0.3) \\ &\quad + 1 \cdot \log_2(0.25) + (1 - 1) \cdot \log_2(1 - 0.25) \\ &\quad + 0 \cdot \log_2(0.2) + (1 - 0) \cdot \log_2(1 - 0.2) \\ &\quad + 0 \cdot \log_2(0.1) + (1 - 0) \cdot \log_2(1 - 0.1)] \\ &= 0.798 \end{aligned}$$

A further information-theoretic measure is the *information score* (Kononenko and Bratko, 1991).

Definition 21: Information score and relative information score.

Let the real class of instance $\mathbf{x}_i$ be y_i . Let the prior probability of that class be $p(y_i)$. Let the predicted score for that class be p_i . The *information score* (I) for the case $\mathbf{x}_i$ is defined as

$$I(\mathbf{x}_i) = \begin{cases} -\log_2 p(y_i) + \log_2 p_i & \text{if } p_i \geq p(y_i) \\ \log_2(1 - p(y_i)) - \log_2(1 - p_i) & \text{if } p_i < p(y_i) \end{cases} \quad (21)$$

The *relative information score* (I_r) is the ratio of the average information score over all n test cases $\mathbf{x}_i$ and the entropy of the prior class distribution,

$$I_r = \frac{\frac{1}{n} \sum_{i=1}^n I(\mathbf{x}_i)}{-\sum_{k=1}^K p(y_k) \log_2 p(y_k)} \quad (22)$$

where n denotes the number of test cases, and K denotes the number of classes.

$I(\mathbf{x}_i)$ is positive if $p_i > p(y_i)$, negative if $p_i < p(y_i)$, and zero if $p_i = p(y_i)$. The information score takes into account the class prior probabilities and thereby accounts for the fact that a high accuracy can be easily achieved in tasks with a very likely majority class (Lavrač et al., 1997). For the introductory example, the information score is calculated as follows.

$$I(\mathbf{x}_1) = -\log_2 0.5 + \log_2 0.95 = 0.926$$

$$I(\mathbf{x}_2) = -\log_2 0.5 + \log_2 0.80 = 0.678$$

$$I(\mathbf{x}_3) = \log_2(1 - 0.5) - \log_2(1 - 0.25) = -0.585$$

$$I(\mathbf{x}_4) = -\log_2 0.5 + \log_2 0.60 = 0.263$$

$$I(\mathbf{x}_5) = -\log_2 0.5 + \log_2 0.50 = 0$$

$$I(\mathbf{x}_6) = -\log_2 0.5 + \log_2 0.55 = 0.138$$

$$I(\mathbf{x}_7) = -\log_2 0.5 + \log_2 0.30 = 0.485$$

$$I(\mathbf{x}_8) = \log_2(1 - 0.5) - \log_2(1 - 0.25) = -0.585$$

$$I(\mathbf{x}_9) = -\log_2 0.5 + \log_2 0.80 = 0.678$$

$$I(\mathbf{x}_{10}) = -\log_2 0.5 + \log_2 0.90 = 0.848$$

$$I_r = \frac{\frac{1}{10}(0.926 + 0.678 - 0.585 + 0.263 + 0 + 0.138 + 0.485 - 0.585 + 0.678 + 0.848)}{-0.5 \log_2 0.5 - 0.5 \log_2 0.5} = 0.2846$$

Cohen's kappa measures the agreement between two raters on a categorical variable (Cohen, 1960). Thus, if we assume that the real class labels are due to some unknown generating process, we can use this measure to compare how well the predictions of a model agree with that process (i.e., reality). This agreement is of course already quantified in the accuracy (Eq. (1)); however, accuracy does not take into account that an agreement could be coincidental. Cohen's kappa adjusts the accuracy by calculating the probability of random agreements.

Definition 22: Cohen's kappa.

Cohen's kappa (κ) is defined as

$$\kappa = \frac{P_0 - P_e}{1 - P_e} \quad (23)$$

where P_0 is the probability that the model's predicted class labels agree with the real class labels, and P_e is the probability of random agreement.

P_0 is estimated as the proportion of correctly predicted class labels, i.e., the accuracy. The probability of random agreement is estimated as follows: the probability that the classifier predicts a case as a positive is $P_+^c = \frac{TP+FP}{n}$. The probability that a case is really a positive is $P_+^r = \frac{TP+FN}{n}$. Hence, the probability that both agree just by chance on the positive cases is the product $P_+^c \cdot P_+^r$. It is of course assumed that the process which generates the real class labels is independent of the model. Analogously, we calculate the probability of random agreement on the negative cases, and we obtain the probability of total random agreement as

$$P_e = \frac{TP + FP}{n} \cdot \frac{TP + FN}{n} + \frac{FN + TN}{n} \cdot \frac{FP + TN}{n} \quad (24)$$

where n is the total number of test cases. For the introductory example (Fig. 2), $\kappa = \frac{3+1}{10} \cdot \frac{3+2}{10} + \frac{2+4}{10} \cdot \frac{1+4}{10} = 0.50$.

Ranking Measures

Ranking performance refers to how well the model orders the positive cases relatively to the negative cases based on the class membership score. There exist various graphical methods for representing ranking performance. Fig. 4(a) shows the gain chart of the introductory example (Fig. 2), which plots the cumulative class on the y -axis and the ranking index of the corresponding instance on the x -axis. For example, if we classify the 4 top-ranked instances as positives, then we classify 3 instances correctly, in contrast to only 2 instances that we expect to predict correctly by random guessing; hence, the gain is 1 correct prediction.

In Fig. 4(a), the red line indicates the expected number of correct positive predictions (for a given number of predicted instances) by using random guessing. The *average gain* is a summary statistic of the gain chart.

Fig. 4 (a) Gain chart and (b) lift chart for the introductory example (Fig. 2). The red line indicates the expected gain or lift for a random guesser.

Definition 23: Average gain.

Let the test cases be ranked based on decreasing values of their class membership scores $p_i = P(y_i = 1 | \mathbf{x}_i) = C(\mathbf{x}_i)$. Let Δg_j denote the difference between the gain of the trained model C , $g_c(j)$, and the gain of the null model, $g_{\text{null}}(j)$, when the j top-ranked instances are classified as positives,

$$\Delta g_j = g_c(j) - g_{\text{null}}(j) \quad (25)$$

The *average gain* is the average of all differences in gain,

$$\bar{g} = \frac{1}{n} \sum_{j=1}^n \Delta g_j \quad (26)$$

where n is the total number of test cases.

For example, assuming that the null model is random guessing, we calculate the average gain for the introductory example as follows: $\bar{g} = \frac{1}{10}[(1 - 0.5) + (2 - 1) + (2 - 1.5) + (3 - 2) + (4 - 2.5) + (4 - 3) + (4 - 3.5) + (5 - 4) + (5 - 4.5) + (5 - 5)] = 0.75$. Geometrically, the average gain is the average distance between the gain curve and the red line in Fig. 4(a).

Fig. 4(b) shows the corresponding lift chart. Note that the expected lift for random guessing is 1.

Definition 24: Average lift.

Let the test cases be ranked based on decreasing values of the class membership scores $p_i = P(y_i = 1 | \mathbf{x}_i) = C(\mathbf{x}_i)$. Let $\text{lift}(j)$ denote the lift when the j top-ranked cases are classified as positive. The *average lift* is defined as

$$\bar{\text{lift}} = \frac{1}{n} \sum_{j=1}^n \text{lift}(j) \quad (27)$$

where n is the total number of test cases.

For the introductory example, we calculate the average lift as follows (see Fig. 2):

$$\bar{\text{lift}} = \frac{1}{10}(2 + 2 + 4/3 + 3/2 + 8/5 + 4/3 + 8/7 + 5/4 + 10/9 + 1) = 1.427$$

The *receiver operating characteristic* (ROC) curve is one of the most widely used graphical tools to plot the performance of a binary classifier (Bradley, 1997; Fawcett, 2004; Fawcett, 2006; Flach, 2010; Berrar and Flach, 2012). The ROC curve depicts the trade-offs between the false positive rate (or 1 minus specificity, shown on the x-axis) and the true positive rate (or sensitivity or recall, shown on the y-axis). These trade-offs correspond to all possible binary classifications that result from any dichotomization of the ranking scores. The points connecting the segments of the ROC curve are called *operating points*, and they correspond to the possible classification thresholds.

Fig. 5(a) shows the ROC plot for the introductory example. The diagonal red line is the expected ROC curve of a random guesser. The area under the diagonal is 0.5. Hence, any “good” model should produce a ROC curve above the red line, with an *area under the curve* (AUC) larger than 0.5. The AUC is a commonly used summary statistic of the ROC curve and can be interpreted as a conditional probability because it is equivalent to a Wilcoxon rank-sum statistic (Bamber, 1975; Hanley and McNeil, 1982; Hanley and McNeil, 1983): given any randomly selected positive and negative case, the AUC is the probability that the model assigns a higher score to the positive case (i.e., ranks it before the negative case). Following Hilden’s notation (Hilden, 1991), the AUC is defined as follows.

Fig. 5 Three different methods for the graphical representation of ranking performance. (a) ROC plot, showing the ROC curve (solid line) and the ROC convex hull (with dotted lines spanning the concavities). The red line is the expected performance of a random guesser. (b) TPR-FPR plot. (c) Precision-recall plot. The point marked by a white circle results from thresholding the ranking scores at t_5 .

Definition 25: Area under the ROC curve.

Let $P(p_+ > p_- | \mathbf{x}_+ \text{ and } \mathbf{x}_-)$ denote the probability that a randomly selected actual positive case, $\mathbf{x}_+$, has a higher ranking score, p_+ , than a randomly selected negative case, $\mathbf{x}_-$, i.e., $p_+ > p_-$. Here, a *higher* ranking score means that $\mathbf{x}_+$ is ranked *before* $\mathbf{x}_-$. Let $n_+ > 0$ be the number of positive instances and $n_- > 0$ be the number of negative instances, and $n = n_+ + n_-$. Let $\text{TPR}(t_i)$ and $\text{FPR}(t_i)$ denote the true positive rate and false positive rate for a threshold t_i , respectively, where $k = n + 1$ is the number of possible thresholds. The *area under the ROC curve* (AUC) is defined as

$$\text{AUC} = P(p_+ > p_- | \mathbf{x}_+ \text{ and } \mathbf{x}_-) = \int_0^1 \text{TPR}(t_i) d\text{FPR}(t_i) \quad (28)$$

From an empirical ROC curve, the AUC can be calculated as

$$\text{AUC} = \frac{S_- - 0.5n_-(n_+ + 1)}{n_+n_-} \quad (29)$$

where S_- is the sum of the ranks of the negative instances.

For the introductory example, we obtain $S_- = 3 + 6 + 7 + 9 + 10 = 35$, $n_- = 5$, $n_+ = 5$, and $\text{AUC} = \frac{35 - 0.5 \cdot 5 \cdot 6}{5 \cdot 5} = 0.8$, which corresponds to the shaded area in Fig. 6(a). Note that the expected AUC of a random model is 0.5, whereas the AUC of a perfect model is 1.

A closely related measure is the *Gini index*, which is defined as follows.

Definition 26: Gini index or Gini coefficient.

The *Gini index* (or *Gini coefficient*) is defined as

$$\text{Gini} = \frac{A}{B} \quad (30)$$

where A is the area between the ROC curve and the diagonal line from (0,0) to (1,1), and B is the area above that line, with $B = 0.5$.

The Gini index can be easily derived from the AUC. Consider Fig. 6(b). A is the purple area. As $\text{AUC} = A + 0.5$, we have $A = \text{AUC} - 0.5$. Then, since $\text{Gini} = \frac{A}{0.5} = 2A$, we obtain $\text{Gini} = 2 \cdot \text{AUC} - 1$. For the introductory example, we obtain $\text{Gini} = 2 \cdot 0.8 - 1 = 0.6$.

A further measure that can be derived from the ROC curve is the *area under the ROC convex hull* (AUCH). The ROC convex hull is the hull that encloses the operating points of the ROC curve (Flach, 2010; Provost and Fawcett, 2001). The line segment (0,0) to (0,0.4), the dotted lines, and the segment (0.6,1.0) to (1.0,1.0) in Fig. 5(a) represent the convex hull for the introductory example; the corresponding AUCH is shown in Fig. 6(c).

Definition 27: Area under the ROC convex hull.

The *area under the ROC convex hull* (AUCH) is the area under the curve that results from the interpolation between the following k points in ROC space, which are ordered based on increasing values of their abscissa: the origin $(x_i, y_i) = (0,0)$, the minimum set of points spanning the concavities, and the point (1,1). The AUCH can be calculated for an empirical ROC curve by using the trapezoidal rule,

Fig. 6 Different graphical representations of ranking performance for the model from the introductory example (cf. Fig. 2). The point (0.2, 0.6) in ROC space and the point (0.6, 0.75) in precision-recall space result from thresholding the ranking scores at t_5 . (a) ROC plot, with $AUC=0.8$. The red line is the expected performance of a random guesser. (b) ROC plot, with Gini index $= \frac{0.3}{0.5} = 0.6 = 2 \cdot AUC - 1$. (c) ROC plot, with $AUCH=0.88$. (d) Precision-recall plot, with a trapezoidal estimator for the area under the curve, $AUCPR_{\min}=0.6476$.

$$AUCH = \sum_{i=1}^{k-1} y_i(x_{i+1} - x_i) + 0.5(y_{i+1} - y_i)(x_{i+1} - x_i) \quad (31)$$

For the introductory example, we obtain $AUCH=0.88$.

In Fig. 5(b), the true positive rate (TPR) and false positive rate (FPR) are plotted as a function of the classification threshold in a TPR-FPR plot, from which the Kolmogorov-Smirnov statistic can be derived.

Definition 28: Kolmogorov-Smirnov statistic.

The Kolmogorov-Smirnov statistic (KS) is the maximum value of the absolute difference between two cumulative distributions. When we assess the ranking ability of a model, these distributions are given by the true positive rates, $TPR(t_i)$, and false positive rates, $FPR(t_i)$, for all classification thresholds t_i .

$$KS = \max\{|TPR(t_i) - FPR(t_i)|\} \quad (32)$$

The KS statistic has a simple geometrical interpretation as the maximum distance between the TPR and FPR curves. In Fig. 5(b), the distance between the TPR and FPR curve is maximal for threshold t_6 , and $KS=0.8-0.6=0.2$. The KS statistic was shown to be sensitive to various types and levels of noise (Berrar, 2014; Berrar, 2016) and is therefore not recommended for model evaluation and comparison. A closely related but more robust measure is the truncated average Kolmogorov-Smirnov statistic (taKS) (Berrar, 2014), which calculates the average distance between the TPR- and FPR-curves.

Definition 29: Truncated average Kolmogorov-Smirnov statistic.

Let $\text{TPR}(t_i)$ and $\text{FPR}(t_i)$ denote the true positive and false positive rate for a classification threshold t_i , respectively, where $k=n+1$ is the number of possible thresholds. The *truncated average Kolmogorov-Smirnov statistic* (taKS) is the average distance between the TPR- and FPR-curves, excluding the start- and endpoints (0,0) and (1,1),

$$\text{taKS} = \frac{1}{k-2} \sum_{i=2}^{k-1} [\text{TPR}(t_i) - \text{FPR}(t_i)] \quad (33)$$

For the introductory example, we obtain $\text{taKS} = \frac{1}{9} \cdot [(0.2 - 0) + (0.4 - 0) + (0.4 - 0.2) + (0.6 - 0.2) + (0.8 - 0.2) + (0.8 - 0.4) + (0.8 - 0.6) + (1 - 0.6) + (1 - 0.8)] = 0.33$.

In precision-recall plots (Fig. 5(c)), the precision is plotted as a function of the recall (or true positive rate or sensitivity). A frequently used summary measure of a precision-recall plot is the *average precision*, which corresponds to the *area under the precision-recall curve* (AUCPR).

Definition 30: Average precision or area under the precision-recall curve.

Let n_+ be the number of positive instances and n_- be the number of negative instances, with $n_+ > 0$ and $n_- > 0$ and $n_+ + n_- = n$. Let $h_+(t_i)$ denote the hits, i.e., the number of positive instances at or above the threshold t_i , $i=1 \dots k$, where $k=n+1$ is the number of possible classification thresholds. Accordingly, let $h_-(t_i)$ denote the number of negative instances at or above the threshold. The recall at threshold t_i is $r(t_i) = \text{TPR}(t_i) = \frac{h_+(t_i)}{n_+}$. The precision is $p(t_i) = \frac{h_+(t_i)}{i-1}$ for $i > 1$ and 0 for $i=1$. The *average precision* (AP) is the area under the precision-recall curve,

$$\text{AP} = \int_0^1 p(t_i) dr(t_i) \quad (34)$$

From an empirical precision-recall curve, AP can be calculated by using the trapezoidal rule,

$$\text{AP} = \sum_{i=1}^k p(t_i) \Delta r_i = \sum_{i=1}^k p(t_i) [r(t_i) - r(t_{i-1})] \quad (35)$$

with $r(t_0)=0$.

For the introductory example, we calculate the average precision as follows (see Fig. 2): $\text{AP} = 1 \cdot 1/5 + 1 \cdot (2/5 - 1/5) + 2/3 \cdot (2/5 - 2/5) + 3/4 \cdot (3/5 - 2/5) + 4/5 \cdot (4/5 - 3/5) + 4/6 \cdot (4/5 - 4/5) + 4/7 \cdot (4/5 - 4/5) + 5/8 \cdot (5/5 - 4/5) + 5/9 \cdot (5/5 - 5/5) + 5/5 \cdot (5/5 - 5/5) = 0.835$.

The term “average precision” could be misunderstood as the average over the precisions resulting from all possible thresholds; in the introductory example, this average is $\frac{1}{10} \cdot (1 + 1 + 2/3 + 3/4 + 4/5 + 4/6 + 4/7 + 5/8 + 5/9 + 5/10) = 0.714$. Note that the expected AP of a random model is $\frac{n_+}{n}$, whereas the AP of a perfect model is 1.

From an empirical precision-recall plot, it is not obvious how the area should be calculated because the precision normally does not change monotonically with increasing recall (cf. Fig. 5(c)) (Boyd et al., 2013; Davis and Goadrich, 2006). From a plot like the one shown in Fig. 5(c), we can construct different curves by interpolating through different points, and consequently, we obtain (slightly) different areas under the curve, which can be calculated by using *trapezoidal estimators*.

Definition 31: Trapezoidal estimators of the area under the empirical precision-recall curve.

Let $p_{\min}(t_i)$ and $p_{\max}(t_i)$ denote the minimum and maximum precision, respectively, for a recall at threshold t_i , $i=1 \dots k$, where $k=n+1$ is the number of possible thresholds. The *area under the empirical precision-recall curve* (AUCPR) can be estimated by $\text{AUCPR}_{\min\max}$, $\text{AUCPR}_{\max}$ (upper trapezoid), or $\text{AUCPR}_{\min}$ (lower trapezoid), where

$$\text{AUCPR}_{\min} = \sum_{i=1}^{k-1} \frac{p_{\min}(t_i) + p_{\min}(t_{i+1})}{2} [r(t_{i+1}) - r(t_i)] \quad (36)$$

$$\text{AUCPR}_{\min\max} = \sum_{i=1}^{k-1} \frac{p_{\min}(t_i) + p_{\max}(t_{i+1})}{2} [r(t_{i+1}) - r(t_i)] \quad (37)$$

$$\text{AUCPR}_{\max} = \sum_{i=1}^{k-1} \frac{p_{\max}(t_i) + p_{\max}(t_{i+1})}{2} [r(t_{i+1}) - r(t_i)] \quad (38)$$

The *mean average precision* (MAP) is the extension of AP to more than two classes (Beitzel et al., 2009). MAP is simply the arithmetic mean of the average precisions, which we obtain by considering each class in turn as the positive class. MAP is a widely used performance measure in information retrieval (Beitzel et al., 2009).

Evaluating an Obtained Value of a Performance Measure

Once we have the value of our performance measure, how should we interpret it? For example, assume that we obtain a sensitivity of 0.80 – how do we know whether this is a good result or not? The performance may of course be evaluated based on domain

expert knowledge. If such knowledge is not available, however, then we could consider the statistical significance of the observed performance, keeping of course in mind the caveats and pitfalls of the p -value (Berrar, 2017).

Confidence intervals are always more meaningful than p -values. The statistical literature contains various approaches for calculating a confidence interval for a proportion. Here, we will present only two of them: a *simple asymptotic confidence interval* based on the normal approximation and the *exact Clopper-Pearson confidence interval*. We will assume that the prediction for an instance $\mathbf{x}_i$ is independent from the prediction for another instance $\mathbf{x}_j$, $i \neq j$. Also, we will assume that the test instances were randomly sampled from the target population. Note that, in practice, both assumptions may be violated.

Significance Testing With Random Permutation Tests

Random permutation tests are non-parametric Monte Carlo procedures that make fewer distributional assumptions than parametric significance tests. Such tests can be used to assess the statistical significance of an observed result. There exist various random permutation tests; for an overview, see (Good, 2000; Ojala and Garriga, 2010). In our context, the basic procedure of a random permutation test is as follows:

1. Train the classifier on the training set and apply it to the test set. Calculate the value v of the statistic of interest, i.e., the value of the performance measure.
2. Randomly permute the class labels of the training set. Thereby, any association between the data set attributes and the class labels is destroyed.
3. Retrain the classifier on the *permuted* training set and apply it to the test set. Calculate the statistic again (i.e., the value w_i of the performance measure of interest).
4. Repeat steps (2) and (3) many times (e.g., $k = 10000$ times) to generate the empirical distribution of the statistic under the null hypothesis of no association between the class labels and the data set attributes.

The p -value is defined as the probability of observing results as extreme as (or more extreme than) the observed results, given that the null hypothesis is true (Berrar, 2017; Sellke et al., 2001). The p -value quantifies the compatibility between the null hypothesis and the observed result: the smaller the p -value, the smaller is the evidence in favor of the null hypothesis (i.e., the less compatible is the null hypothesis with the observed result). We can calculate a p -value for our observed performance v by counting how many values w_i are at least as extreme as v . For example, assume that $v = 0.80$ is the observed sensitivity. Let us further assume that we performed 10000 random permutations and that among these, 300 values w_i are at least 0.80. Then the one-sided, empirical p -value is $\frac{300}{10000} = 0.03$. Thus, under the null hypothesis that there is no association between the attributes and the class labels, the probability of observing a sensitivity of at least 0.80 is 0.03.

Approximate Confidence Interval for a Proportion

Let p denote the (unknown) proportion in a population. For a sufficiently large sample, the sample proportion, $\hat{p}$, is approximately normally distributed with a mean of p . The standard deviation of the sampling distribution of the sample proportion (i.e., the standard error of the sample proportion) is $\sigma_{\hat{p}} = \sqrt{\frac{p(1-p)}{n}}$, which is estimated as $s_{\hat{p}} = \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}$. The *Wald interval* is an approximate $(1-\alpha)100\%$ confidence interval for a population proportion (Wald and Wolfowitz, 1939).

Definition 32: Wald confidence interval.

Let $\hat{p}$ denote a proportion estimated from a sample of size n . If $n\hat{p} > 5$ and $n(1 - \hat{p}) > 5$, then an approximate asymptotic $(1-\alpha)100\%$ confidence interval for the population proportion p is given by the *Wald interval*,

$$\hat{p} \pm z_{1-\alpha/2} \cdot \sqrt{\frac{\hat{p}(1-\hat{p})}{n}} \quad (39)$$

where $z_{1-\alpha/2}$ is the quantile of the standard normal distribution for probability $1-\alpha/2$.

For example, a 95% Wald interval for the sensitivity in the introductory example is calculated as follows. With $TP=3$ and $FP=2$, we obtain $\hat{p} = \frac{3}{5}$ (= sensitivity). The interval is then

$$\hat{p} \pm z_{1-\alpha/2} \cdot \sqrt{\frac{\hat{p}(1-\hat{p})}{n}} = 0.6 \pm 1.96 \cdot \sqrt{\frac{0.6 \cdot 0.4}{5}} = 0.6 \pm 0.4294 = [0.1706, 1.0294] \quad (40)$$

We see that the upper bound exceeds 1, which, obviously, is the maximum sensitivity; hence, the confidence interval includes values that are impossible. The approximation is not good because the conditions $n\hat{p} = 5 \cdot 0.6 > 5$ and $n(1 - \hat{p}) = 5 \cdot (1 - 0.6) > 5$ do not hold; therefore, an exact confidence interval should be calculated.

Exact Confidence Interval for a Proportion

An exact confidence interval based on the F -distribution is given by the Clopper-Pearson interval (Clopper and Pearson, 1934).

Definition 33: Exact Clopper-Pearson confidence interval.

Let $\hat{p} = \frac{r}{n}$ denote a proportion estimated from a sample of size n . An exact $(1-\alpha)100\%$ Clopper-Pearson confidence interval for the population proportion p is given by

$$\left[\frac{r}{r + (n - r + 1)F_{1-\alpha/2; 2(n-r+1), 2r}}, \frac{(r + 1)F_{1-\alpha/2; 2(r+1), 2(n-r)}}{(n - r) + (r + 1)F_{1-\alpha/2; 2(r+1), 2(n-r)}} \right] \quad (41)$$

where $F_{1-\alpha/2; df_1, df_2}$ is the quantile function of the F -distribution with df_1 and df_2 degrees of freedom.

For instance, a 95% confidence interval for the sensitivity in the introductory example is calculated as follows.

$$\left[\frac{3}{3 + (5 - 3 + 1)F_{1-0.05/2; 2(5-3+1), 2 \cdot 3}}, \frac{(3 + 1)F_{1-0.05/2; 2(3+1), 2(5-3)}}{(5 - 3) + (3 + 1)F_{1-0.05/2; 2(3+1), 2(5-3)}} \right] = [0.1466, 0.9473]$$

Bootstrap Percentile Confidence Interval

To derive a confidence interval analytically, it is necessary to calculate the standard error of the sample statistic, which is not trivial for the more intricate performance measures. When conventional parametric confidence intervals are difficult to calculate or when their assumptions are violated, deriving a *bootstrap confidence interval* is an interesting alternative. The *bootstrap* is a data resampling method for assessing the accuracy of statistical estimates (Efron, 1981; Efron and Tibshirani, 1994). There exist different types of bootstrap confidence intervals (Efron, 1987; DiCiccio and Efron, 1996). One of the simplest ones is the *percentile bootstrap* (Efron, 1981). The basic procedure for deriving a bootstrap percentile confidence interval is as follows (Berrar and Dubitzky, 2013):

1. From the available learning set, L , which contains a total of n instances, generate a bootstrap set, B , by randomly and uniformly sampling n instances with replacement.
2. Repeat step (1) b times to generate B_i bootstrap sets, $i = 1 \dots b$.
3. Build model C using the set B_i as training set, and apply C to the corresponding out-of-bag set T_i , which contains the elements from L that are not in B_i .
4. Calculate the value of the performance measure $\hat{\theta}_i$ from T_i .
5. Repeat steps (3) and (4) for all b bootstrap sets and calculate all $\hat{\theta}_i$, $i = 1 \dots b$.

Definition 34: Bootstrap percentile confidence interval.

Let L denote a learning set from a population. Let θ denote the unknown value of a performance measure for a predictive model C for that population. Let B_i denote the i^{th} bootstrap set (i.e., i^{th} training set) that was sampled uniformly with replacement from L , and let the number of instances in B_i and L be the same. Let T_i denote the i^{th} out-of-bag test set, with $T_i = L \setminus B_i$. The model C is trained on B_i and then applied to T_i . Let $\hat{\theta}_i$ denote the resulting value of the performance measure. A $(1-\alpha)100\%$ *bootstrap percentile confidence interval* (CI_{boot}) for θ is given by

$$CI_{\text{boot}} = [\hat{\theta}_{\alpha/2}, \hat{\theta}_{1-\alpha/2}] \quad (42)$$

where $\hat{\theta}_{\alpha/2}$ and $\hat{\theta}_{1-\alpha/2}$ are the $\alpha/2$ and $1 - \alpha/2$ percentiles, respectively, of the empirical distribution of $\hat{\theta}$.

In R, bootstrap confidence intervals can be generated with the function `boot.ci` of the package `boot` (Davison and Hinkley, 1997; Canty and Ripley, 2017).

Discussion

Which performance measure should be used in practice? A single “best” measure does not exist, as the different measures quantify different aspects of the performance. However, accuracy or error rate are not really meaningful when the classes are highly imbalanced. For example, assume that the class ratio is 9:1 in both the training and test set. A model that always predicts the majority class (i.e., a majority voter) is expected to achieve an accuracy of 90%, although it has not learned anything from the data. Performance measures that are based on a probabilistic interpretation of error are, in general, preferable to measures that rely on a single classification threshold. For example, let us assume that model A made the predictions shown in Table 2, and let us assume that model B made the same predictions, except that case #8 was misclassified with a score of 0.79. This is clearly a worse prediction than that of model A , which produced the score 0.75 for case #8. However, for t_5 , the threshold-based measures would not discriminate between A and B , in contrast to the measures that are based on a probabilistic interpretation of error.

Graphical tools such as ROC curves, lift charts, TPR-FPR plots, and precision-recall curves generally paint a clearer picture of the predictive performance than summary statistics. Clearly, it is often desirable to use a single value, for example, in order to tabulate the results of various models so that they can be ranked from best to worst, which is commonly done in data mining competitions. However, we have to keep in mind that we lose important information when we condense a two-dimensional plot into a single scalar. Thus, whenever possible, performance plots are preferable to scalars.

Ranking measures that are derived from such plots are popular evaluation measures; particularly, the AUC is widely used in machine learning. In contrast to accuracy, for example, the AUC is relatively robust to class imbalances and other types of noise (Berrar, 2014; Berrar, 2016). Therefore, the AUC is not a bad choice as a performance measure, although several shortcomings have

been pointed out (Hilden, 1991; Adams and Hand, 1999; Hand, 2009; Parker, 2013). For example, consider a drug discovery study that aims at ranking thousands of chemical compounds based on their toxicological effect. Here, it is typically possible to follow up on only a small number of top-ranked compounds, which should be predicted very accurately. By contrast, it may be irrelevant how well the lower-ranked compounds were predicted. This is also known as the *early retrieval problem*: although we are interested in only the top-ranked instances, the AUC also reflects the quality of the predictions of the remaining instances, which may not be interesting.

There exists an equivalence between ROC curves and precision-recall curves, in the sense that they contain the same points for the same predictive model (Davis and Goadrich, 2006). However, for data sets with highly imbalanced classes, precision-recall curves are more informative than ROC curves because precision-recall curves emphasize the performance with respect to the top-ranked cases (Saito and Rehmsmeier, 2015). In other words, if the correctness of the few top-ranked instances matters most (like in the mentioned drug discovery study), then precision-recall curves are preferable to ROC curves. This might explain why the average precision is more commonly used than the AUC in information retrieval (Su *et al.*, 2015). For data sets with highly imbalanced classes, the average precision (Definition 30) is therefore recommended as performance measure.

Closing Remarks

If a predictive model is developed for a concrete application, then it is usually clear which performance measure matters most. On the other hand, if the general usefulness of a new learning algorithm is to be assessed, then the choice of the most appropriate measure is often not obvious. In that case, reporting several measures can be meaningful. Graphical tools, such as ROC or precision-recall curves, are generally preferable to summary measures. For highly imbalanced classes, the average precision is the recommended performance measure, which is also easily extended to more than two classes as mean average precision (MAP).

Importantly, the performance measure in the training phase should be the same as the measure in the validation and test phase, since a model that was optimized to achieve, say, a high accuracy on the training set is not necessarily expected to achieve, say, a low logloss on the test set. There are further important aspects that need to be considered when we evaluate a predictive model or learning algorithm, such as the choice of benchmark data sets, data resampling strategies, statistical tools to compare different models or algorithms, etc. These aspects are beyond the scope of this article; for a more in-depth discussion, see (Japkowicz and Shah, 2011).

Natural Language Processing Approaches in Bioinformatics

Xu Han and Chee K Kwoh, Nanyang Technological University, Singapore

© 2019 Elsevier Inc. All rights reserved.

Introduction

The quantity of biomedical literature is expanding at an increasing rate. As of 2017, over 23 million references to biomedical literature are included in the MEDLINE database, and this number is growing at the rate of more than 700,000 each year (see “Relevant Websites section”). With such high-speed growth, it has become more and more challenging for biomedical researchers to keep up to date with all the latest advancements within their own research fields. To lessen the burden of this information overload, more and more sophisticated *biomedical natural language processing* (BioNLP) systems are becoming available. Before we discuss the BioNLP in details, we introduce the historical evolution of the natural language processing (NLP) domain and the rise of statistical natural language processing, followed by some of the common NLP sub-problems and their applications to the biomedical text. Finally we discuss some of the advanced topics on the applications of active learning method to the biomedical NLP systems, in order to solve the lacking of training data issue for such systems.

The Historical Evolution of NLP

NLP began as the intersection of artificial intelligence and linguistics in the 1950s. Originally the NLP is distinct of the information retrieval (IR), which aims to establish principled approaches to search various contents such as scientific publications, library records, news-wires. And in Schütze *et al.* (2008) there is an excellent introduction of the topic of IR. In 1956, Chomsky published the theoretical analysis of language grammars (Chomsky, 1956), which estimated the difficulty of the problem in NLP. The analysis leads to the creation of the context-free grammar (CGF) (Chomsky, 1959), which is widely used to represent programming-language syntax.

Up to the 1980s, most parsing approaches in NLP systems were based on complex sets of symbolic and hand-crafted rules. However, there is the problem of ambiguous parses applying to the natural language, as the rules are of large size, unrestrictive nature and ambiguity. The ambiguous parses means that multiple interpretations of a word sequence were possible, as the grammar rules became unmanageably numerous and they were interacting unpredictably.

Starting in the late 1980s, more and more statistical NLP methods are applied to the NLP problems, these methods introduce machine learning algorithms for the language processing (Chomsky, 1957). For examples, in statistical parsing, the parsing-rule proliferation is addressed by the probabilistic CFGs (Klein and Manning, 2003a), where the individual rule is associated probabilities that is estimated through machine-learning on annotated corpora. Thus, the broader yet fewer rules replace the numerous detailed rules, and disambiguation is achieved through referring to the statistical-frequency information contained in the rules. There are other approaches that build the probabilistic rules based on the annotated data. For instance in Quinlan (2014), the researchers build decision trees from feature-vector data, and the statistical parser determine the ‘most likely’ parse of a sentence/phrase, where the statistical parser need to be trained on the domain-specific training data and is context-dependent. For instance, the Stanford Statistical Parser trained with the Penn Treebank, which is the annotated Wall Street Journal articles, will not be suitable for biomedical text. For the topic of statistical NLP, Manning provides an excellent introduction in Manning and Schütze (1999).

NLP Sub-Problems and Applications to Biomedical Text

The research area in the NLP can be broadly divided into two layers: the syntax layer and the semantics layer. A general summarization of the sub-problems and tasks that are covered in our discussions is illustrated in the Fig. 1. Our discussions in the subsequent sections follow the order of the tasks in the figure.

Pre-Processing and Syntactic Layer

In this section, we introduce a fundamental pre-processing step, text normalization, in the NLP. It is a set of tasks that convert the text into a more convenient and standard form. We then discuss a set of tasks that are targeted on the syntactic layer analysis, including language modeling, part-of-speech tagging, text chunking and syntactic parsing.

Text normalization

Text normalization refers to the tasks of converting the text into a more convenient and standard form. These tasks include *tokenization*, *lemmatization*, *stemming*, *sentence segmentation*. The task of *tokenization* is to separate out or tokenizing words from the running text. In the English language, the words are often separated from each other by the whitespace. However in some

Fig. 1 The syntax layer and the semantics layer of natural language processing in the bioinformatics.

applications of NLP, separating by whitespace is not sufficient. For instance, we may need to separate the *I'm* into the two words: *I* and *am*. In this case, a tokenizer need to expand the *clitic* contractions that are marked by apostrophes. A clitic is a part of word that can't stand on its own, and only occurs when attached to another word. In other applications, a tokenizer need to treat a multi-word expression as a single token, although there is whitespace in the expression. For example, the 'United States' is recognized as a large token. This type of recognition is intimately correlated in the named entity recognition task, as discussed in Section "Named entity recognition".

One commonly used tokenization standard is the *Penn Treebank tokenization* standard, which is adopted in the parsed corpora by the Linguistic Data Consortium (LDC). In this standard, hyphenated words are kept together and the clitics and all punctuation are separated out. One example of the tokenization is given below:

Input: "The San Francisco-based restaurant," they said, "doesn't charge \$10".

Output: “The San Francisco-based restaurant”, “they said
, “does n’t charge \$10”.

For other languages such as Chinese or Japanese, where there is no spaces between words, the task of tokenization becomes more difficult.

Another task in text normalization is the *lemmatization*, which is the task to determine whether the input words have the same root, despite their surface differences. For instance, the words *eat*, *ate*, *eaten* and *eats* are the lemma *eat*. A lemmatizer maps from all these word to *eat*. One of the approaches for lemmatization is the *morphological parsing* of the word, where the word is regarded as built up from smaller meaning-bearing units called *morphemes*. Two broad types of morphemes are the stems and the affixes. The stems denotes the central morpheme of the word, and they defines the main meaning of the word; while the affixes carry the ‘additional’ information for the word. So the word ‘apples’ have two morphemes: the stem ‘apple’ and the affix ‘-s’. The task of *stemming* is a simpler form of lemmatization, where the suffixes are stripped from the end of the word. For instance, the word *looking* is converted to *look* after stemming. One of the commonly used stemmer is the *Porter Stemmer*, proposed in 1980 (Porter, 1980). The algorithm is based on a set of rewrite rules that applied to words in cascade, where the output of a certain step is fed as input for the subsequent step. Detailed rule lists of the Porter Stemmer and the source code of the program is provided in the author’s homepage (see “Relevant Websites section”).

Sentence segmentation is another step in the text processing, where the sentence splitter use the punctuation to segment a text into sentences. While the question marks and exclamation points are relative unambiguous for sentence segmentation, some punctuation mark, such as the period, may pose ambiguity between abbreviation and sentence boundary to the task. To solve this issue, sentence splitter work in general by building a binary classifier, either based on rules or machine learning, to decides if a period is the abbreviation or the sentence boundary.

Currently a wide variety of useful tools for tokenization and normalization is available, such as the Stanford Tokenizer (see “Relevant Websites section”) or specialized tokenizers for Twitter (O’Connor *et al.*, 2010), or for sentiment (see “Relevant Websites section”). NLTK (see “Relevant Websites section”) is an essential tool that offers useful Python libraries of many algorithms including text normalization and corpus interfaces for the NLP domain. We refer the interested reader to the publication in Indurkha and Damerau (2010) for a survey of text preprocessing.

Language modeling with N-grams

One strength for the statistical NLP is the ability to make statistical inference. For example, given a precedent word, the statistical NLP can assign a probability to each possible next word. The prediction of upcoming words, or assigning the probability of the whole sentence, is crucial in task like *handwriting recognition*, where the words need to be identified in noisy and ambiguous input. The models that assign probabilities to sequences of words are referred to as *language models*. The simplest model that assigns probabilities to sentences is the *N-gram* model. An N-gram is a sequence of N words: A 2-gram (or bi-gram) consists of two words; while a 3-gram (or trigram) have three words. One example is given as follows:

Input: Please give me that apple.

Bi-gram:

Please give

,

give me

,

me that

,

that apple

Trigram:

Please give me

,

give me that

,

me that apple

By splitting the text of the corpus into N-gram, we can get a statistical estimation for the conditional probability for a word given its preceding words. For instance in bi-gram model, we get the estimation of the probability $P(\text{me}|\text{give})$, where the word 'me' is preceded by the word 'give', by counting the occurrence of the bi-gram 'give me' in the corpus. In practical computation, we always use the log probability, to avoid the numerical underflow issue if too many probabilities are multiplied. To evaluate the language models, one commonly used metric is *perplexity*, which is the inverse probability of the test set, normalized by the number of words.

By using text from the web, it is possible to build extremely large language models. In 2006 Google released a very large set of N-gram counts, including N-grams (1-grams through 5-grams) from all the five-word sequences that appear at least 40 times from 1024, 908, 267, 229 words of running text on the web; this includes 1176, 470, 663 five-word sequences using over 13 million unique words types (Franz and Brants, 2006).

As the language modeling assign probabilities, one practical consideration is to keep a language model from assigning zero probability to the unseen N-grams, which may cause the whole sentence probability to be zero and affects the subsequent log-calculation. One remedy is to shave off a bit of probability mass from some more frequent N-grams and give it to the N-grams were never seen. This modification is called smoothing or discounting.

A wide variety of different language modeling and smoothing techniques were proposed in the 80s and 90s, including Good-Turing discounting first applied to the N-gram smoothing at IBM by Katz (Nadas, 1984; Church and Gale, 1991) Witten-Bell discounting (Witten and Bell, 1991), and varieties of class-based N-gram models that used information about word classes. Two commonly used toolkits for building language models are SRILM (Stolcke, 2002) and KenLM (Heafield, 2011; Heafield et al., 2013). SRILM offers a wider range of options and types of discounting, while KenLM is optimized for speed and memory size, making it possible to build web-scale language models. Another important technique is language model adaptation, where we want to adaptation combine data from multiple domains. For example, we might have less in-domain training data for a particular domain, but have much more data in the general domain. In this case, one practical solution is the language model adaptation, as reported in the publications (Bulyko et al., 2003; Bacchiani et al., 2004, 2006; Bellegarda, 2004; Hsu, 2007; Liu et al., 2013).

Part-of-speech tagging

Part-of-speech is also known as POS, *word classes* or *syntactic categories*. In the English language, some common types of *part-of-speech* include noun, verb, pronoun, preposition, adverb, conjunction, participle and article. Knowing whether a word is noun or verb can provide much information about the POS tag for its neighboring word. For instance, the nouns are usually preceded by determiners and adjectives, and verbs are often preceded by nouns. This makes the POS tagging an important component in the syntactic parsing. In applications such as named entity recognition and information extraction (introduced in Sections "Named entity recognition" and "Event and relation extraction"), the POS tags of the words are useful features for the NLP systems. *Part-of-speech tagging* is the process of assigning a POS tag to each word of the input text. Generally the step of tokenization is adopted before the POS tagging step in NLP, as the tags are also applied to punctuation.

Most current NLP applications on English use the 45-tag Penn Treebank tag set (Marcus et al., 1993). Generally the POS information is represented by placing the POS tags after each word, delimited by a slash. One example sentence after the POS tagging is shown below:

Input: The grand jury commented on a number of other topics.

Output: The/DT grand/JJ jury/NN commented/VBD on/IN a/DT number/NN of/IN other/JJ topics/NNS/.

As each word can have more than one possible part-of-speech, the problem of POS-tagging is to choose the proper tag for the context. The training and testing datasets for the statistical POS tagging algorithms are often the corpora labeled with POS tags. For the English language, some of the most commonly used corpora are the *Brown* corpus, the *WSJ* corpus and the *Switchboard* corpus. The Brown corpus is based on 500 written texts from different genres published in the United States in 1961, while the WSJ corpus contains words published in the Wall Street Journal in 1989, and the Switchboard corpus mainly focus on telephone conversations

that are collected in 1990–1991. Regarding to the construction process of these corpora, they are created by applying an automatic POS tagger on the text of the corpus, and then the POS tags are manually curated by the human annotators. And there is two commonly used algorithms for POS-tagging: the Hidden Markov Model (HMM) (Church, 1988) and the Maximum Entropy Markov Model (MEMM) (Ratnaparkhi, 1996).

In the POS tagging for biomedical domain, there are the GENIA tagger (Tsuruoka *et al.*, 2005a) and the MedPost (Smith *et al.*, 2004), which are specifically designed for tagging biomedical text. And one commonly used corpus for training the POS tagger is the GENIA Corpus (Kim *et al.*, 2003). Recently, the FLORS POS tagger is reported in Schnabel and Schütze (2014), which is based on domain adaptation method and shows significantly better performance than some of the state-of-the-art POS taggers, including the SVMTool tagger (Giménez and Marquez, 2004) that based on support vector machine (SVM), the bidirectional log-linear model based Stanford tagger (Toutanova *et al.*, 2003), the HMM-based TnT tagger (Brants, 2000).

Text chunking

Text chunking is the process of identifying and classifying the flat, non-overlapping segments of a sentence that constitute the basic non-recursive phrases corresponding to the major parts-of-speech found in most wide-coverage grammars. This set typically includes noun phrases, verb phrases, adjective phrases, and prepositional phrases; in other words, the phrases that correspond to the content-bearing parts-of-speech. The most common chunking task is to simply find all the base noun phrases in a text.

Since chunked texts lack a hierarchical structure, a simple bracketing notation is sufficient to denote the location and the type of the chunks in the text. One example of a typical bracketed notation is illustrated below:

text chunking: [_{NP} The morning flight] [_{PP} from] [_{NP} Denver] [_{VP} has arrived.]

This bracketing notation makes clear the two fundamental tasks that are involved in chunking: finding the non-overlapping extents of the chunks and assigning the correct label to the identified chunks.

Note that in this example all the words are contained in some chunk. This will not be the case in all chunking applications, as the words in the input text will often fall outside of any chunk. For example, in systems searching for only NPs in their inputs, the output will be as follows:

text chunking: [_{NP} The morning flight] from [_{NP} Denver] has arrived.

State-of-the-art approaches to chunking use supervised machine learning to train a chunker by using annotated data as a training set. A common approach to text chunking is to treat chunking as a tagging task similar to part-of-speech tagging (Ramshaw and Marcus, 1999). In this approach, a small tag set simultaneously encodes both the segmentation and the labeling of the chunks in the input. The standard way to do this is called IOB tagging and is accomplished by introducing tags to represent the beginning (B) and internal (I) parts of each chunk, as well as those elements of the input that are outside (O) any chunk.

We give the IOB tagging result for the example sentence as follows:

input text: The morning flight from Denver has arrived.

IOB tagging: B_NP I_NP I_NP B_PP B_NP B_VP I_VP

Given such a scheme, building a chunker consists of training a classifier to label each word of an input sentence with one of the IOB tags from the tag set. Of course, training requires training data consisting of the phrases of interest delimited and annotated with the proper category. The direct approach is to annotate a representative corpus. However, annotation efforts can be both expensive and time consuming. It turns out that the best place to find such data for chunking is in an existing treebank such as the Penn Treebank (Marcus *et al.*, 1993), as mentioned in the Section “Part-of-Speech tagging”.

Context-free grammar and syntactic parsing

Before we introduce the syntactic parsing, we discuss about the context-free grammar, or CFG, which is formalized by Chomsky (1956) and, independently, Backus (1959). Context-free grammars are the backbone of many formal models of the syntax of natural language, and they are integral to many computational applications, such as grammar checking, semantic interpretation, dialog understanding, and machine translation. They are powerful enough to express sophisticated relations among the words in a sentence, yet computationally tractable that support efficient algorithms to parse sentences with them.

A context-free grammar consists of a set of rules or productions, each of which expresses how the symbols of the language can be grouped and ordered together, and a lexicon of words and symbols. For example, the following productions express that an NP (or noun phrase) can be composed of either a Proper Noun or a determiner (Det) followed by a Nominal; a Nominal in turn can consist of one or more Nouns.

context-free grammar:

$NP \rightarrow DetNominal$

$NP \rightarrow ProperNoun$

$Nominal \rightarrow Noun|NominalNoun$

Context-free rules can be hierarchically embedded, so we can combine the previous rules with others. For instance, the Fig. 2 illustrate how the context-free rules are embedded, to form a parse tree for the phrase “a promoter”.

Similarly, we can build the parse tree for a sentence, as shown in Fig. 3.

A parse tree or syntax tree is an ordered, rooted tree that represents the syntactic structure of a string according to the context-free grammar. The parse trees can be constructed based on the constituency relation of constituency grammars, which is also called the phrase structure grammars, as shown in Fig. 3. However, the parse trees can also be generated based on the dependency grammars. We refer the interested reader to the detailed discussions in Ágel (2006) and Carnie (2012).

Fig. 2 A parse tree for “a promoter”.

Fig. 3 A parse tree for sentence “A promoter initiates the transcription of a gene”.

A treebank is a syntactically annotated corpus where every sentence in the collection is paired with a corresponding parse tree. Treebanks play an important role in parsing, as well as in linguistic investigations of syntactic phenomena. To build a treebank it is possible to manually make the annotation only by linguists, yet such effort is expensive and costly. In general, a wide variety of treebanks have been created through the use of parsers to automatically parse each sentence, followed by linguists to manually correct the parses. One commonly used treebank for syntactic parsing is the Penn Treebank project (whose POS tagset we introduced in Section “Part-of-Speech tagging”).

In statistical NLP, there are many methods to augment the CFG in order to allow the statistical learning for the syntactic parser. One simplest augmentation of the context-free grammar is the Probabilistic Context-Free Grammar (PCFG), also known as the Stochastic Context-Free Grammar PCFG(SCFG), first proposed by Booth (1969). A PCFG differs from a standard CFG by augmenting each rule with a conditional probability. Then the issue is how to learn PCFG rule probabilities. The simplest way is to use a treebank, a corpus of already parsed sentences. Given a treebank, we can compute the probability of each expansion of a non-terminal by counting the number of times that expansion occurs and then normalizing. For the detailed discussions on the statistical learning for the PCFG, we refer the interested readers to the research work in Schabes *et al.* (1988), Schabes (1990), Hindle and Rooth (1993), Klein and Manning (2003b) and Petrov *et al.* (2006).

Semantical Layer

Word sense disambiguation

Word sense disambiguation (or WSD) is the task of selecting the correct sense for a word. In English, one word could have multiple senses. A *sense* (or *word sense*) is a discrete representation of one aspect of the meaning of a word. For instance, the word 'bank' have different aspects of meaning in the two phrases: 'the federal bank' and 'the river bank'. The word sense disambiguation is important to many NLP tasks, such as machine translation and information retrieval. Generally, the WSD algorithm takes a word in context along with a fixed inventory of potential word senses, and return the correct word sense for that use as the output. One approach to the WSD problem is the supervised learning, where the training data that has been hand-labeled with correct word senses are prepared, and then the WSD algorithm extracts features from the text, and a classifier is trained to assign the correct word sense given these features.

The supervised WSD algorithms based on sense-labeled corpora have the best-performing performance for sense disambiguation. However, such labeled training data is expensive and difficult to prepare. One alternative method is to get indirect supervision from dictionaries, thesauruses or similar knowledge bases. And this approach is also called knowledge-based WSD. The most well-studied dictionary-based algorithm for sense disambiguation is the Lesk algorithm, which choose the sense whose dictionary gloss or definition shares the most words with the target words neighborhood (Lesk, 1986; Kilgarriff and Rosenzweig, 2000). The recent high performing systems generally use POS tags and word collocations from a words window (Zhong and Ng, 2010).

One commonly used resource for this approach is the *WordNet*, which consists of three separate databases, one each for nouns and verbs and a third for adjectives and adverbs for the lexical relations. Each database contains a set of lemmas, each one annotated with a set of senses (Kilgarriff, 2000).

Both the supervised approach and the dictionary-based approaches to WSD require large hand-built resources: supervised training sets in one case, large dictionaries in the other.

We can instead use bootstrapping or semi-supervised learning, which needs only a very small hand-labeled training set. A classic bootstrapping algorithm for WSD is the Yarowsky algorithm for learning a classifier for a target word (in a lexical-sample task) (Yarowsky, 1995).

Modern interest in supervised machine learning approaches to disambiguation began with Black (1988), who applied decision tree learning to the task. The need for large amounts of annotated text in these methods led to investigations into the use of bootstrapping methods (Yarowsky, 1995), which needs only a very small hand-labeled training set. Diab and Resnik (2002) give a semi-supervised algorithm for sense disambiguation based on aligned parallel corpora in two languages. For a comprehensive survey article on WSD, we recommend the publication in Navigli (2009), and in Agirre and Edmonds (2007) there is a summary for the state-of-the-art progress in the WSD.

Named entity recognition

One of the fundamental research areas in biomedical information extraction is the named entity recognition (NER) task. Theoretically, the biomedical information extraction includes: (1) the recognition of terms expressing concepts for biomedical entities, for example, the gene names and protein names are to be recognized from the raw text, (2) the extraction of specific relations between biomedical entities, for instance, the discovery of the protein interactions based on the raw text, and (3) the extraction of the more complex types of biomedical information. One example is the widely known GENIA project (see "Relevant Websites section"), which is to uncover the metabolic pathways of the protein NF-kappa B. The NER is a crucial step for other sophisticated applications such as information extraction, since the steps of the entities recognition and linking them to the standardized ontological concepts in the NER are the foundations for accessing the textually described domain-specific information in the information extraction. Even besides information extraction, the NER supports the solution of more complicated tasks in text mining, such as event and relation extraction (de Bruijn and Martin, 2002; Hanisch *et al.*, 2003).

The linking of the terms in raw text with the concepts pre-defined in the ontology is a requirement for the text mining systems. This step is due to fact that the terms are more variable than concepts explicitly represented in the ontology. One example of the common variations is that EGR 1 and EGR 1 and EGR1 all express the same biological concept. Thus if the three variants all appear in the raw text, they all should be considered as the same concept. It is reported that such phenomenon of variance in raw text consists of one third of the total term occurrences (Wacholder, 2003), which suggests the identification of variance may help the recognition of terms in text.

On the other hand, the extraction of synonym and abbreviation comes from the inherent characteristics of terminologies in the biomedical domain. Paralleling the growth of the biomedical literature is the expanding volume of biomedical terminologies. In the current biomedical documents, many biomedical entities have more than one names or abbreviations. The issue has been attracting more and more attention of research, since it would be advantageous to extract the synonyms and abbreviations, so as to aid users in document retrieval in an automatic way. In the current study of biomedical text mining, the synonym and abbreviation extraction is mainly about the extraction of gene names and abbreviations of biomedical terms.

One application of the extraction of synonym and abbreviation is that it can be incorporated into the search engines to improve the search results. For example, one may use the medical abbreviation in using the PubMed to search relevant documents; the search engine, however, can integrate a dictionary of medical abbreviations, based on the dictionary of abbreviations to augment search queries and improve the search results. One thing worth noting is that if an abbreviation, which is well-accepted in a particular domain yet is not included in the maintained dictionary, is encountered in an article, the aim of improving in research results is becoming more difficult to achieve, since the solution of this issue requires the expert knowledge for that particular domain, together with the interpretation of the context of such abbreviation.

The extraction for gene name and protein name synonym is a more challenging problem. One possible way is to construct a synonym list and keep updating it. However, the quality of extracting the list is not guaranteed because of the low precision in extraction systems. (Cohen *et al.*, 2005) has used a pattern extraction approach and co-occurrence analysis to generate a synonym extraction system. Without any NER module for the gene names, the system has a score of 22% in F-measure. Yet with the identification of logical relation, the recall for the system improved by 10%.

The research progress on the NER domain is evaluated through the shared tasks, which is a community-wide competition for the state-of-the-art NER systems. We review some of the latest evaluation competition tasks on NER, including the CoNLL for the general domain, and the BioCreAtIvE for the biomedical domain.

The CoNLL-2003 shared task is one of the most widely used tasks for NER in the general domain. The dataset for the English language is taken from the Reuters Corpus, which consists of Reuters news stories between August 1996 and August 1997 (Sang and De Meulder, 2003). In the data file, one word is contained per line, and the empty lines represent the sentence boundaries. Within each line, four fields are contained: the word, the word's part-of-speech tag, the chunk tag for the word, and the named entity tag for the word.

The named entity tag is defined as follows: the word with O tag means it is outside of named entity; while words with I-XXX tag indicates the opposite, i.e., inside a named entity that is typed XXX. In addition, where two named entities that are of the same type XXX and are adjacent to each other, the named entity tag for the first word is B-XXX. In the shared task, four types of named entities are defined: persons (PER), organizations (ORG), locations (LOC) and miscellaneous names (MISC). An example sentence of the CoNLL-2003 NER task is given in Table 1.

The settings for the shared task are that, learning from the provided training dataset, the text mining system need to recognize the named entities that are contained in the separate evaluation dataset. In the shared task, 16 systems have employed a wide variety of machine learning techniques, including Maximum Entropy Model (Bender *et al.*, 2003), Hidden Markov Model (Florian *et al.*, 2003), AdaBoost.MH (Carreras *et al.*, 2003), memory-based learning (De Meulder and Daelemans, 2003), Transformation-based learning (Florian *et al.*, 2003), Support Vector Machines (Mayfield *et al.*, 2003) and Conditional Random Fields (McCallum and Li, 2003).

The evaluation results in the task are ranging from 69% to 88% in F-measure, while recently, the state-of-the-art Stanford NER system has reported the F-measure of around 90% in the task dataset (Finkel *et al.*, 2005).

Recently, more and more research work has been published on the application of natural language processing and information extraction to the biomedical literature. However, as Hirschman pointed out, each group had addressed different problems on different data sets (Hirschman *et al.*, 2002). Hence it became important to assess the progress of biomedical text mining systematically. Similar to the CoNLL shared tasks, the aim of organizing BioCreAtIvE challenge (Critical Assessment of Information Extraction in Biology) is to support a systematic assessment of the state-of-the-art information extraction systems. However, comparing to the CoNLL shared tasks, the BioCreAtIvE challenge is information extraction in the biomedical domain, which has its own specialty comparing to the general domain.

Two tasks are defined in the BioCreAtIvE II (Smith *et al.*, 2008). The first task assessed the extraction of gene names or protein names, and the linking of gene or protein names into the standardized gene identifiers in the databases for model organisms in biology, including fly, mouse and yeast. The second evaluates the functional annotation, where the participating systems were

Table 1 Example sentence for the CoNLL-2003 NER task

U.N.	NNP	I-NP	I-ORG
Official	NN	I-NP	O
Ekeus	NNP	I-NP	I-PER
Heads	VBZ	I-VP	O
For	IN	I-PP	O
Baghdad	NNP	I-NP	I-LOC
.	.	O	O

given full-text articles and should recognize specific text that supports the annotation for specific proteins with the Gene Ontology (Hirschman *et al.*, 2005).

One aim of BioCreAtIvE challenge is to support the curation process of biological databases. The BioCreAtIvE challenge was built on the KDD Challenge Cup, which is one of the earliest evaluations competitions in the biomedical text mining (Yeh *et al.*, 2003). Similar to the BioCreAtIvE, the KDD Cup also hosts tasks on the curation of biological literature, in particular, the recognition of articles that contain experimental evidence for the gene products of the database Flybase (see “Relevant Websites section”).

27 groups participated in the BioCreAtIvE challenge, and the evaluation results in task 1 are ranging from 80% to 90% in F-measure. Task 2, on the other hand, created a baseline for future research on functional annotation.

From the BioCreAtIvE challenge, interesting questions relevant to biology were raised. The gene name tagging task in BioCreAtIvE is compatible for comparison of similar tasks in other domains. The functional annotation task proposed an aim for biomedical text mining, which is to map complex concepts, which are expressed in raw text, to concepts defined in the ontologies. Overall, the BioCreAtIvE challenge was a major step forward in reflecting the advancements of the applications of text mining into biomedical domain (Krallinger *et al.*, 2008), in particular, the support of curation of biological databases that organize the raw biological data into amenable structures and associate biological data with experimental results contained in published literature.

Event and relation extraction

In the current post genomic era of the biology study, more and more studies have been focused on the relationships between genes and proteins. Through grouping genes by their functional relationships, both the analysis of the gene expression and database annotation can be aided. The grouping is currently divided into two ways. One way is based on how strong their associations are in the raw text. The other way is to use the relations between genes, proteins, or other biological entities and then to extract them from the text. Based on the previous accomplishment, it is suggested that the difficulty in extracting relations is different, as some can be extracted well but others cannot. The relationships that are very general, non-specific such as the gene groups relation between genes are easy to extract; on the other hand, specific relations that depend on their particular context, for example, the process of the GO code assignment in the annotation, remain challenging.

In contrast to NER, which is mainly related to the analysis of individual entity, event and relation extraction is relevant to a pair of, or even multiple, entities. The crucial characteristic of relation extraction is that it involves a pair of entities, which makes the analysis simpler than the event extraction, which is a more general *n*-ary prediction task for arbitrary numbers of arguments. In the structure of an event, there is a *trigger word*, which expresses the main event, and the arguments for the trigger word, which describe the detailed information relevant to the trigger word. The goal of relation extraction is to identify instances of a pre-defined type of relation between a pair of entities. While the types of the entity can be extremely specific, such as a gene, a protein or a drug, the type of relationship can be either highly general, for example, the expression of location for a pair of entities, or very specific such as the expression of the regulatory relationship, including inhibition or activation.

An example of the event and relation extraction is shown in Fig. 4. In the figure, different words are annotated with their corresponding ontological concepts shown in boxes. For instance, the word ‘activin’ is annotated with the ontological concept ‘Protein’. There may exist different types of pre-defined types of events and relations for the words, such as the ‘Activation’ (for the word ‘promotes’) and ‘Protein-Protein Interaction’ (for the word ‘interaction’). Such words with ontological annotations are nodes, while the edges between the nodes represent the detailed relationship between them. For instance, there is relationship of ‘Activation’ (for the word ‘promotes’) that ‘has Agent’ the ‘Protein’ (for the word ‘activin’).

Several approaches to extracting entity relationships have been used. To begin, some researchers use template-based syntactic patterns, which usually are regular expressions generated by domain experts, to extract specific relations from text (Yu *et al.*, 2002). One of the challenges in the hand-craft pattern is that a given event may be expressed in a variety of forms, such as the morphological, syntactic and lexical variations. To improve the performance, some syntactic generalization is often introduced. After the application of hand-craft pattern to extract candidate events, there is often an additional step of consolidation, where task-specific rules are applied to the candidate events. Another method is to use an automatic template. In this method, the templates, which are similar to manually generated regular-expression patterns, are automatically generalized patterns based upon the text close to the entity pairs, which have the relation of interest (Yu and Agichtein, 2003). The third method is a statistical approach that identifies the relationships by comparison to random predictions, evaluating the probability that the concepts will be found near to each other by chance (Friedman, 2002).

Fig. 4 Example of event and relation extraction.

BioNLP-shared tasks (BioNLP-ST)

Similar to the BioCreAtIvE challenge in the NER task, the BioNLP shared tasks series (BioNLP-ST) (Kim *et al.*, 2009, 2016, 2011a; Nédellec *et al.*, 2013) are organized to evaluate the progress of research on information extraction applications in the BioNLP domain. However, the focus of BioCreAtIvE and BioNLP-ST are different. While the BioCreAtIvE challenge assesses the simple representation of protein-protein interactions (PPI), the BioNLP-ST series are more centered on detailed biological relations, such as biological events (Kim *et al.*, 2011b). In addition, while the BioCreAtIvE challenges support the curation of PPI databases, the BioNLP-ST series are intended to support more detailed and structured databases, for example, pathway (Bader *et al.*, 2006) or Gene Ontology Annotation (GOA) databases (Camon *et al.*, 2004).

Among the participating systems in BioNLP-ST 13', only one system, TEES, submitted results for all the tasks except one (Nédellec *et al.*, 2013) and it was the first ranked system in four out of eight tasks, which showed its power in the event and relation extraction tasks. The TEES system is dependent on efficient machine learning approaches and features that are obtained from a full dependency analysis, generated by the applications of full dependency parsers into biomedical domain. For instance, many of the best-performing systems utilize the full dependency parses (Buyko *et al.*, 2009; Kilicoglu and Bergler, 2009; Sebastian *et al.*, 2009; Van Landeghem *et al.*, 2009). The pipeline for the system includes three steps: the first is *trigger recognition*, followed by the step of *argument detection*, the last is the step of *semantic post-processing*. For the trigger recognition step, the reason why the TEES separate the first step from the second step is that the TEES can use methods that are similar to the task of NER, with the exception of identifying the words for event trigger. With such approach, the problem of the detection of event arguments becomes the determination of whether the pairs, in the form of trigger-entity or trigger-trigger, are an instance of event arguments. Such steps are in essence classification tasks. The final step, semantic post-processing, is addressed through the rule-based approach by directly implementing the constraints defined the definition of each Shared Task. We refer the interested reader to the detailed explanation and implementation of TEES in publication in Björne *et al.* (2011) and Björne and Salakoski (2015).

Text summarization

Text summarization is the process of distilling the most important information from a source (or sources) to produce an abridged version for a particular user (or users) and task (or tasks), and the generated summary can successfully imitate summaries generated by human beings, in other words, the summary should be concise and fluent while preserving key information content and overall meaning.

Generally, there are two main approaches to summarizing text documents, the extractive methods and abstractive methods. Extractive text summarization involves the selection of phrases and sentences from the source document to make up the new summary. Techniques involve ranking the relevance of phrases in order to choose only those most relevant to the meaning of the source. Abstractive text summarization involves generating entirely new phrases and sentences to capture the meaning of the source document. This is a more challenging approach, but is also the approach ultimately used by humans. Classical methods operate by selecting and compressing content from the source document.

We refer the interested reader to the book (Mani and Maybury, 1999) for detailed discussions of the text summarization, and the publication in Allahyari *et al.* (2017) for a survey of the text summarization techniques.

In the biomedical domain, the recent shared task on text summarization is the TAC BiomedSumm track (see "Relevant Websites section") held in 2014. The task challenged participants to leverage the set of citation sentences that reference a specific paper ('citations') for summarization, an important problem in BioNLP research (Lu *et al.*, 2007; Jin *et al.*, 2009).

The citations can be seen as a (community created) summary of an academic paper, and the set of citations is taken to summarize the key points of the referenced paper, and so reflects the importance of the paper within an academic community (Nakov *et al.*, 2004; Qazvinian and Radev, 2010), and they offers a new type of context that was not available at the time of authoring of the citation and the collection of citations to a reference paper adds an interpretative layer to the cited text.

Specifically, the track included identifying the text spans in the referenced papers reflecting the citations, classifying those spans into paper facets and then generating summary for the referenced papers based on the community discussion of their citations. This form of scientific summarization could be a component of a User Interface in which a user is able to hover over or click on a citation, which then causes a citance-focused faceted summary of the referenced paper to be displayed, or a full summary of the referenced paper taking into account the citations in all citing papers for that reference paper. Finally, this form of scientific summarization would allow a user to read the original reference paper, but with links to the subsequent literature that cites specific ideas of the reference paper.

Advanced Topics: Applications of Active Learning to Biomedical NLP Systems

The growth in the biomedical literature is paralleled by the growth in biomedical terminology, in which a single biomedical entity may have many different names and descriptions. The construction of an *ontology* is one way to address this issue of normalization. An ontology is a conceptual model that aims to support a consistent and unambiguous formal representation of a specific knowledge domain (Stevens *et al.*, 2000). Biomedical ontologies map biological concepts to their semantics, such as biological definitions and their relations to other biological concepts. By creating a commonly acceptable conceptual model, the adoption of an ontology ensures that data sets are machine readable and processable.

Many sophisticated BioNLP systems are based on machine learning. Machine learning studies the construction and analysis of systems that can learn from data. In BioNLP, machine learning algorithms can be designed and implemented to learn language patterns or rules from the limited amount of ontologically annotated biomedical documents. However, the research and implementation of BioNLP systems often require ‘gold-standard’ annotated corpora (Bada and Hunter, 2011), which contain biomedical documents that have been manually annotated with terms and relations defined in ontologies. The annotated corpora can subsequently be applied to the training of BioNLP systems (Tsuruoka *et al.*, 2005b).

To construct the ‘gold-standard’ annotated corpus, usually a group of human annotators first randomly select a pool of biomedical documents to be annotated. Based on their domain expertise, the annotators then manually identify and label the instances of document words or phrases with the proper ontological concepts defined in the ontology. After the manual annotation phase, an inter-annotator agreement (IAA) score, which measures the consistency of the expert annotators, is calculated for the annotated corpus. For instance, in a corpus construction project, acceptable IAA score may fall within the range of 66%–90%, depending on the difficulty of the annotation tasks and the level of annotator discrepancies (Thompson *et al.*, 2009). The annotated corpus could then be used for the training and evaluation of machine learning models. Such methodology is often referred as *passive learning*, and the documents are typically randomly chosen. However, the whole process of constructing annotated corpora is time-consuming and costly, as it requires substantial and tedious effort from the human annotators. Therefore, it is particularly valuable to construct the annotated corpus as quickly and economically as possible, using a directed sampling process (active learning), where the learner interactively queries the annotator for information about unannotated documents, and chooses the most informative document from which to learn, in order to generate as good a learner as possible with a minimum number of annotated documents.

Active learning is a subfield of supervised machine learning, in which the learning algorithm actively chooses the data it learns, in order to generate a learner that works as well as possible with the minimum amount of annotated data provided by the human annotator (Settles, 2012). This is especially useful for many supervised learning tasks, where it is very difficult, and time-consuming to obtain annotated data from an annotator. For instance, in the domain of information extraction, sophisticated information extraction systems should be trained using annotated documents. To produce such labeled documents, annotators who often have extensive knowledge in the specific domain markup entities and relations in text, which is a particularly time-consuming process. It is reported that, even for simple newswire stories, it can take half an hour or more to locate entities and relations (Settles *et al.*, 2008). And for tasks in other domains, such as annotating gene and protein mentions for biomedical information extraction, annotators must possess additional domain expertise.

Active learning has been studied in many natural language processing applications, such as word sense disambiguation (Chen *et al.*, 2013), named entity recognition (Tomanek and Hahn, 2009a,b, 2010), speech summarization (Zhang and Yuan, 2014) and sentiment classification (Kranjc *et al.*, 2015; Li *et al.*, 2012). Two popular approaches exist in the active learning method: the uncertainty-based approach (Lewis and Catlett, 1994) and committee-based approach (Seung *et al.*, 1992). The uncertainty-based approach is to label the most uncertain samples by using an uncertainty scheme such as entropy (Fu *et al.*, 2013). It has been shown, however, that the uncertainty-based approach may have worse performance than random selection (Schütze *et al.*, 2006; Tomanek *et al.*, 2009; Wallace *et al.*, 2010).

In biomedical information extraction, uncertainty-based active learning has been applied to the extracting PPIs task. For instance, Cui *et al.* (2009) adopted an uncertainty sampling-based approach to active learning, and Zhang *et al.* (2012) proposed maximum-uncertainty based and density-based sample selection strategies. While the extraction of PPI is concerned with a single event of type PPI, recent biomedical event extraction tasks (Kim *et al.*, 2009) involve multiple event types, and even hundreds of event types in the case of the Gene Regulation Ontology (GRO) task of BioNLP-ST’13 (Kim *et al.*, 2013).

In contrast, by using an ensemble approach, the committee-based active learning approach selects documents such that the documents’ label classification results mostly disagree with each other in the results of the committee of classifiers. The committee-based approach, however, has several issues in its application to event and relation extraction. As the event and relation extraction task is fundamentally different from applications of active learning in the other domains, as they are mainly focused on document classification. However, in a event extraction task, such as PPI extraction or gene regulation identification, the systems have to identify not only event keywords (also known as trigger words, e.g., regulation), but also event participants (also known as event arguments, e.g., gene or protein) within the input text; in addition, the systems need to extract relations between entities that are pre-defined in the given ontology. Hence, even if some systems provide confidence scores for their recognized events; these scores do not correspond to the probability that a particular event type is semantically present in a document, which is the probability of determining if a document belongs to that event type, as required in committee-based active learning.

Recently, there is research work, reported in Han *et al.* (2016a), of applying a committee-based active learning approach to biomedical event and relation extraction, by using an informativity score based system that evaluates the probability that a particular event type is semantically present in a document. The active learning method is evaluated using the BioNLP Shared Tasks datasets; and the results show that the event extraction system can be more efficiently trained than with other baseline methods.

The underlying principle in these methods is similar: to select the samples that are most ‘informative’, according to a certain measurement, to the underlying machine learning system. Moreover, there is a trend in active learning methods to consider whether the selected samples are ‘representative’ or not, as non-representative samples, such as outliers, may cause overfitting and undermine the training performance of the supervised learning framework. To select ‘representative’ examples and avoid outliers, different approaches have been proposed. For instance, information density may be used to guide the selection of documents (Settles and Craven, 2008). This approach explicitly models the distribution of average similarity for all the data point in the data

set with density weights, and has been shown to outperform uncertainty-based approaches. The informativeness of a sample is weighted by its average similarity to all other samples, and a sample with high similarity has high weight. This method was designed to avoid spending too much time on annotating outliers, which have low information density. We refer the interested reader to the detailed explanation in publication in [Settles and Craven \(2008\)](#).

On the other hand, there are also active learning methods that integrate unsupervised clustering techniques ([Kang et al., 2004](#); [Zhu et al., 2008](#); [Qian and Zhou, 2010](#)). For instance, [Kang et al. \(2004\)](#) they first clustered all samples, before active learning, by applying the k-means algorithm until it converges to form the clusters with pre-defined number, and selected documents close to the cluster centroids as the initial set for annotation, instead of beginning with a random subset of samples. In [Zhu et al. \(2008\)](#) they further develop this idea by incorporating information density to guide the document selection, implementing a k-nearest-neighbor-based density weight in order to circumvent the risk of selecting outliers.

Recently, there is research work of, reported in [Han et al. \(2016b\)](#), that select a mixture of both ‘representative’ and ‘informative’ documents from the clustering results. Rather than merely selecting the cluster centroids for annotation, the researchers select examples that are either near cluster centroids or near cluster boundaries, in order to improve the active learning performance.

Note that, the active learning method is similar to positive-unlabeled (PU) learning in that they both try to learn from the unlabeled dataset. In particular, the PU learning method first partitions the unlabeled dataset into four sets, namely, the reliable negative set, RN, the likely positive set, LP, the likely negative set, LN and the weak negative set, WN. Yet in active learning, such partitioning of the unlabeled dataset is not performed. We refer the interested reader to the publication in [Yang et al. \(2012, 2014\)](#).

Conclusion

In this article, we provide an overview of historical evolution of the natural language processing and summarize the common NLP sub-problems, together with their research progress in bioinformatics. Additionally, we discuss an advanced topic of applying the active learning into the NLP systems, in order to solve the practical issue of lacking training data for the systems.

Text Mining Basics in Bioinformatics

Carmen De Maio, Giuseppe Fenza, Vincenzo Loia, and Mimmo Parente, University of Salerno, Fisciano, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

One of the main goal of Text Mining (TM) is to discover relevant information in the text by transforming it into data that can then be analyzed. However, though correct, this definition does not convey the real relevance, efficacy, and role that TM plays in bioinformatics. Actually, the scientific production in this research field has reached huge proportions, even if we separately consider single research sub-fields. In the last decade, the research articles collected in public repositories, such as PubMed, are growing very much. Fig. 1 points out that the number of publications per year on Bioinformatics are doubled in 2014 with respect to 2008. In addition, if we consider the cumulative number of publications the growth became impressive. In this scenario, the availability of massive unstructured material raised the interest for literature-based applications in order to carry out useful findings for further scientific investigations in bioinformatics.

The excessive competition in science may also have adverse effects on research integrity, causing also the urgent need to discover and discard *bad science*, see e.g. Fanelli, 2009. In particular, in biomedicine it is fundamental to recover all the valid scientific literature concerning molecules, genes, proteins, tissues, cells, etc., to find the origin and causes of diseases. In Fig. 2, we can see the growing trend of applying text-mining.

TM, as a mere discipline, has already won the challenge for the identification, normalization, and disambiguation of key entities like the above mentioned, and it also has demonstrated to be a winning strategy to investigate the relations among those entities (Ananiadou et al., 2010). However, it is also important to note that recent developments and advances in the field of TM have put forward the limits of what is commonly considered *basics* knowledge in the area. The aim of this survey is hence to expose the up-to-date basics of TM, enhanced with recent developments in successful application scenarios.

Just to provide an evidence of the most trending topics related to text-mining in bioinformatics, we have collected articles published on PubMed in the period 2006–2017 by indexing abstracts and keywords, and we have extracted the word-cloud shown in Fig. 3. As we can see, the most relevant trends regard Machine Learning applications, Information and Relation Extraction, Named Entity Recognition, Information Retrieval and others.

Summary

The article is structured as follows: Section “Fundamentals” introduces the methods addressing linguistic analysis and other tasks for enabling text-mining applications; Section “Applications” provides a list of some existing solutions (e.g., Information Retrieval, Summarization, etc.) for each category of text-mining application in bioinformatics; Section “Evaluation Techniques and Metrics” provides the methods to evaluate text mining applications; then, Section “Case Study: Text Mining for Simplifying Biomedical Literature Browsing” illustrates a case study of literature-based application simplifying biomedical literature browsing. Finally, the conclusions summarizes the key points of the article.

Fig. 1 The number of publications in PubMed on Bioinformatics.

Sentence Detection

Sentence detection (or Sentence Boundary Detection – SBD) is the problem of NLP to identify the start and the end of a sentence in a given document. Generally, it is a rather complex task because of the presence of misspellings, punctuation errors, and incomplete phrases. In bioinformatics, this task is even more complicated mainly due to the following concerns:

- The ambiguity in the use of periods, as closing an abbreviation (Prof.), marking the individual letters of an abbreviation (t.b.d.), indicating the rational parts of the real numbers (2.18) and so on.
- The mining of periods, like when the word *Q.E.D* is written at the end of a phrase. In this case, the punctuation defines the end of both the abbreviation and the sentence.
- Some general rules for delimiting the boundaries of a sentence are not always valid in biomedical texts, e.g., a sentence may start with a lowercase letter.
- The presence in the biomedical field of many acronyms and abbreviations.

Let us underline that correct sentence detection impacts also on other NLP tasks determining the structural role of words in sentences and phrases, such as Part-of-Speech tagging.

Tokenization

Tokenization is the problem of NLP devoted to dividing the text into a set of tokens. Tokens are approximately words but include also punctuation marks, date, time, fraction, person title, range and so on. The process uses a set of regular expressions to identify the token delimiters and special cases, occurring more frequently in biomedical text. The technique of tokenization can be deployed in different hierarchical flavours: text can be broken up into paragraphs, sentences, words, syllables, or phonemes. Generally, one token refers to one term or to one word, but it could also be an instance of a sequence of characters grouped together as a unique semantic unit. As an example, *type* is the class of tokens that contains the same sequence of characters.

As with sentence detection, even for tokenization, there are several problems to deal with. To understand whether to delete a punctuation character or not because it is not part of the word to be extracted as tokens: for example, the period at the end of the sentence. In many cases, when the period is part of an abbreviation or of a numeric expression, it should not be deleted. Even the case of the dashes is complex to deal with because in the biomedical field it can mean the absence of an element, that is, “- water” (less water) and thus it means to eliminate not only the dashes but also the next token. On the other hand, it can be a compound word and then everything becomes a unique token. The different applications have to hence find the right strategy to not cause errors in the mining of the text, thus a preliminary analysis could be foreseen, according to what counts as a token depending on the application domain.

Part-of-Speech Tagging

The technique of Part-of-Speech (PoS) tagging consists in assigning a role, among verb, noun or adjective, to every word occurring in the phrases. Most used approaches can be categorized as follows.

- *Rule-based taggers* (Greene and Rubin, 1971), tries to tag every word using hand-written rules: for example, a word which follows a determiner and an adjective must be a noun.
- *Stochastic (probabilistic) approach* (Màrquez and Rodriguez, 1998), adopts a training corpus to choose among the most feasible tags for a word. All these methods use massively the Markov models.
- *Transformation-based approach*, combine the two previous approaches. The most likely tag on a training corpus is considered, and then a particular set of rules is adopted to assess the validity of the tag, and in case it is modified to something else. The rules generated in this fashion, are then added to the set and taken into consideration in the next tag selection. One example of such tagger is the Brill tagger (Brill, 1992).

The PoS tagging on medical texts is complicated by the ambiguity of words. A term that can generally be an adjective, in the medical domain, may refer to a very precise medical condition, such as the word “cold”. Various specialized tagging tools for biomedical text exist in the literature, including MedPOST (Smith *et al.*, 2004) and LingPipe.

Stemming and Lemmatize

Stemming and Lemmatize both reduce inflectional and corresponding derivated related forms of a word to a common base form.

Stemming eliminates variations of grammatical forms of the same word (e.g., “connection” – “connect”, “computing” – “compute”, etc.). The stemming process is finalized to improve the effectiveness of the text process to avoid mismatches both in prefixes and suffixes. In fact, these can cause a mismatch or even miss of relevant information. Lemmatization is close to stemming. It removes inflectional endings and returns the lemma that is the base form or the dictionary form of a word. As an example, for the token “saw”, the lemmatization technique returns both “see” or “saw”, depending on whether the token is used as a verb or as a name.

Syntactic Structure

The syntactic structure is the problem of NLP of determining the structural role of words in sentences and phrases. It requires grammatical analysis of sentences and organizes the words in a manner showing the relationship among them. For example, in the text “Studying genetic circuit dynamics with fluorescence microscopy”, the phrase “with fluorescence microscopy” is associated with “studying”, not with “genetic circuit dynamics”. Obviously, this interpretation is very simple for humans, but more difficult for computers, because there are many syntactic ambiguities. The ambiguity in a sentence can contain an ambiguous phrase but with only one or many different interpretation.

Text Disambiguation

Text Disambiguation is the process that identifies the sense, i.e. the meaning, of a word in a sentence, when the word has multiple meanings. In the biomedical domain, it is a very critical task, since when the words are ambiguous, clearly the process of identification of key entities, like genes, proteins, cells, diseases, and so on is much more difficult.

An example of a very effective disambiguation tools is Wikify! (Mihalcea and Csomai, 2007). Used in biomedical scenarios, it extracts a model to represent the text. By exploiting the wikification services, it determines the meaning of the text and from this extracts the main concepts (De Maio *et al.*, 2015a). In particular, by using the Wikipedia knowledge base, it extracts a set of pairs $\langle \text{topic}, \text{relevance} \rangle$, where *topic* is a Wikipedia article, representing the meaning of the content, along with a corresponding membership degree, called *relevance*, ranging in the $[0,1]$ interval. For example, the following sentence is extracted from a PubMed article (the wikified terms will be bold-ed and underlined in the snippet):

“Extremely atrophic maxillae can be considered the most important indication for three-dimensional maxillary reconstruction. Different bone-augmentation techniques have been suggested to accomplish this. [...]”

For the above example, the following pairs $\langle \text{topic}, \text{relevance} \rangle$ are given as output which characterize the meaning of the text:

1. $\langle \text{Maxilla}; 0.93 \rangle$,
2. $\langle \text{Atrophy}; 0.83 \rangle$,
3. $\langle \text{Reconstructivessurgery}; 0.73 \rangle$,
4. $\langle \text{Threedimensionalspace}; 0.71 \rangle$,
5. ...

Applications

Some of the most investigated applications of text mining in Bioinformatics are listed below:

- Information Retrieval (IR), devoted to obtain relevant information from a collection of information resources and a user query;
- Document Classification (DC), which assigns one or more classes or categories to a document;
- Named Entity Recognition/Normalization (NER/NEN), devoted to extract named entity from unstructured or semi-structured machine-readable documents;
- Summarization (SUM), which synthesizes input text covering all contents of analyzed documents;

In this section, we detail text mining applications for the biomedical domain by introducing their underlying functional goals and existing solutions at the state of the art. In addition, we will describe (see Section “Others Applications”) some other applications of text-mining not categorized in the classes aforementioned.

Information Retrieval

Over the years different approaches have been studied and explored in the field of IR. The basic keyword-based IR approach simply checks the presence or absence of the words in the query input. More recent researches use mathematical techniques to calculate the relevance of a document and how much a given keyword reflects the actual relevance of a given document with respect to the query. Others expand the user’s queries with related synonyms or alternative names into one conceptual query, based on a controlled vocabulary.

The large volume and the rapid growth of biomedical literature represent a significant barrier for biomedical data retrieval. A set of IR applications in biomedical domain is listed in Table 1, each along with features and distinguishing functionalities.

Many applications such as PubMed and EuropePMC have a local database on which to search the scientific manuscripts. PubMed (see Relevant Website), gives access to open source full text articles and abstracts from the MEDLINE database, and does not include the full-text of journal articles but only provides short summaries. This is different from EuropePMC policy that processes full-text documents. Other applications, like PolySearch2, integrate multiple databases containing both text and sequence data. This application identifies relationships between biomedical entity such as human diseases, genes, proteins, and so on. A similar approach is PIE the search (Protein Interaction information Extraction) that retrieves Protein-protein interactions from PubMed or from other manually provided scientific articles (see Relevant Website section for PubMed, EuropePMC, PolySearch).

Table 1 Recent IR applications

Name	Content	Description
PubMed (McEntyre and Lipman, 2001)	Abstract	Given a user's query, retrieves related scientific publications.
GoPubMed (Doms and Schroeder, 2005)	Abstract	Retrieves information matching the query with biomedical background knowledge
PolySearch2 (Liu <i>et al.</i> , 2015)	Abstracts, databases	Retrieves information according to particular patterns of queries
Europe PMC (Consortium <i>et al.</i> , 2014)	Full text	Explore protein, gene, species and disease records directly from articles
PIE (Kim <i>et al.</i> , 2012)	Query	Finds protein-protein interaction articles from PubMed

Table 2 Recent DC applications

Name	Content	Description
MaxMatcher (Zhou <i>et al.</i> , 2006)	Documents	Dictionary-based biological concept extraction
BioDi (Chebil <i>et al.</i> , 2013)	Documents	Classifies biomedical documents with the MeSH ontology
MetaMap (Aronson and Lang, 2010)	Documents	Maps biomedical documents to the UMLS Metathesaurus concepts

Additional features are related to the classification of results based on contextual information. An example is provided by *GoPubMed* that hierarchically classifies retrieved documents. In particular it assigns each document to a concept of a domain specific ontology or a thesaurus, i.e., Gene Ontology or Medical Subject Headings (MeSH). This assignment to ontology concepts facilitates the navigation among the returned documents, by reducing the search time (see Relevant Website for *GoPubMed*, Gene Ontology, MeSH and Gene Ontology).

Further details on tools for information retrieval from the biomedical literature can be found in Roberts *et al.* (2016).

Document Classification

The search of biomedical documentations plays an important role in biomedical research because much information exists in the form of scientific publications. Furthermore, the number of biomedical publications grows rapidly and consequently it becomes difficult for researchers to quickly find the biomedical publications of interest. A solution is represented by the automatic classification of scientific publications.

Document Classification (DC) is the process of classifying a document as belonging to one or more categories or classes. Documents may be classified according to a very simple feature, like their subjects, or according to other attributes such as document type, author, printing year, etc. Thus, automated biomedical document classification, aiming to identify publications relevant for a specific research field, is an important task that has attracted much interest in the years (Huang and Lu, 2016; Jiang *et al.*, Effective; Lakiotaki *et al.*, 2013; Wu *et al.*, 2017). Table 2 lists recent DC applications in the biomedical domain. MaxMatcher and MetaMap are biological concept extractor, that extract all concepts belonging to Unified Medical Language System (UMLS) meta-thesaurus in order to accordingly classify the documents. Similarly, BioDi that classifies documents with the Medical Subject Headings (MeSH) thesaurus (see Relevant Website section for MaxMatcher and MetaMap).

Named Entity Recognition/Normalization

Named entity recognition (NER) arranges specific semantic classes, so called named entity, in a text such as the names of persons, organizations, places, etc. In biomedicine, the most studied entities have been gene and protein names. Also others have been studied as well, including disease and drug names, cells and types and other terms in the biomedical domain.

The application of NER activity in biomedical information extraction is one of the most important tasks (Han *et al.*, 2016; Lossio-Ventura *et al.*, 2016; Yu *et al.*, 2016). The accuracy of this process is crucial for follow-up researches.

The early biomedical NER approaches (listed in Table 3) are typically classified into three main categories, several of which are widely applied:

- *Rule-based approaches* consist in the manually or automatically construction of rules or patterns matching them in literature to find entities of interest (Yu *et al.*, 2016; Lai *et al.*, 2016). Example is *PPinterfinder*.
- *Lexicon-based approaches* consist in the usage of lexicons, dictionaries (e.g., names, aliases, symbols, etc.) to find specific terms in the analyzed text (Mrabet *et al.*, 2016; Dong *et al.*, 2016). Examples are *FACTA+*, and *G-Bean*.
- *Machine learning based approaches* consist in automatically learn to find entities using specific features that distinguish between features for the training set and those for the testing set (Vijay and Sridhar, 2016; Al-Hegami *et al.*, 2017). Examples are *PIE*, *PolySearch2*, *SCAIVIEW*, and *PCorral* (see Relevant Website section for *PPinterfinder*, *FACTA+*, *PIE*, *PolySearch2*, *SCAIVIEW*, *PCorral*).

Table 3 Recent NER applications

Name	Content	Description
PIE (Kim <i>et al.</i> , 2012)	Query	Finding protein-protein interaction articles from PubMed
PolySearch2 (Liu <i>et al.</i> , 2015)	Full-text	Extracts relations between diseases, genes, drugs, metabolites and toxin
G-Bean (Wang <i>et al.</i> , 2014)	Abstracts	Query documents in database
SCAIView (Malhotra <i>et al.</i> , 2015)	Abstracts	Searches for genes related to sclerosis and programs and drugs aimed
FACTA + (Tsuruoka <i>et al.</i> , 2011)	Abstracts	Discovers and visualizes indirect relations between biomedical concepts
PCorral (Li <i>et al.</i> , 2013)	Protein name	Merges IR and IE (information extraction) from MEDLINE database
PPInterFinder (Raja <i>et al.</i> , 2013)	Query + concepts	Extracts information about protein – protein Interactions from MEDLINE abstracts

Table 4 Recent SUM applications

Name	Content	Description
EntityRank (Schulze and Neves, 2016)	Abstract	Graph-based summarization algorithms for multi-document summarization for the biomedical domain
LTR (Shang <i>et al.</i> , 2014)	Full-text	A summarization method based on learning to rank

A research trend close to NER activity is the Named Entity Normalization (NEN) that is the activity to normalize all named entities in the text. It returns a specific label that is an entry of a domain specific database, ontology and so on. In biomedicine, this activity has been widely studied and explored in the research field of genes and proteins, with a certain success degree (e.g., many species have genes with the same name) (Leaman and Lu, 2016; Lou *et al.*, transition).

Summarization

Summarization (SUM) is the activity that takes in input a document or a set of documents, and outputs a synthesis of analyzed text that covers all the contents of the documents. The increasing amount of available biomedical publications makes the summarization a very important task because it is very hard to quickly find the right information. Considered that, generally, a search in PubMed for example for the gene *p53* returns about 50.000 publications, the summarization process provides more benefits regarding coverage and speed for future scientific searches. Furthermore, the use of domain knowledge to disambiguate domain specific terms is fundamental to create accurate summaries.

Examples (see Table 4) of recent SUM applications in biomedical domain are *EntityRank* and *LTR* (Learn To Rank Summary). The former works only on abstracts from articles retrieved on PUBMED and provides summaries specific to the users information needs. Differently, the latter provides a gene summary extraction analyzing the full-text document. Moreover it approaches the summarization activity as a ranking problem and applies learning to rank methods to automatically accomplish this task.

Others Applications

Others text-mining applications on biomedical literature are emerging, providing novel and useful services. One of this novel application is the expert finding whose goal is to select the right expert of a certain topic. Some solutions to find biomedical experts already exists, such as GoPubMed (Doms and Schroeder, 2005), eTBLAST (Errami *et al.*, 2007) and Jane (Schuemie and Kors, 2008), whose most important weakness is that they are not natively conceived to support experts finding, given as input the topic query. In fact, Jane and eTBLAST take a title or abstract as input, and output the most similar publications, relevant journals, and experts. More recently, BMExpert (Wang *et al.*, 2015) mines MEDLINE documents by considering the relevance of documents with respect to the input topic, and the associations between documents and experts, because, for the biomedical publication, the order of the authors is important.

Another application is the question-answering (Q&A), which returns an answer for a given question. Q&A initially found the best answer by performing data- and text-mining from the database, while more recently uses also unstructured resources. Q&A requires complex natural language queries understanding. It typically involves subtasks, such as, determining the type of questions (e.g., YES/NO, WH, choice, etc.) and, consequently, the type of the expected answers (e.g., time?, location?, person?), or finding documents containing the answer. Moreover, to address biomedical question-answering there is a need to use domain specific linguistic resources, such as Unified Medical Language System (UMLS), a controlled vocabulary unifying over 100 dictionaries, National Center for Biomedical Ontology (NCBO), a collaborative ontology repository, and so forth. For instance, UMLS is used in (Takahashi *et al.*, 2004) a question answering system using semantic information of the terms that were selected from the returned documents, to rank candidate answers and to determine their similarity degree. Let us note that the degree of difficulty varies by varying the question type. In the biomedical domain, the definition of questions has been extensively studied, see Lin

and Demner-Fushman (2005), Yu and Wei (2006), Yu *et al.* (2007). BioSquash (Shi *et al.*, 2007) is a question answering system based on multi-document summarization system for biological questions. Some other works address more specific biological questions, as in (Lin *et al.*, 2008) that focuses on questions about events in biomolecular scenarios, like the interactions between genes and proteins.

The last trend emphasizes the interest in extracting relations among entities cited for semantically annotating the text by using NLP and text-mining (De Maio *et al.*, 2014). Actually, to improve text-mining applications, based on biomedical literature analysis, there is a need to perform a deeper information extraction. In fact, it is required to extract assertions about protein-protein interactions, diseases and their treatments, nanomaterial and its toxicity because of the growing amount of unstructured findings published so frequently (Hunter *et al.*, 2008; Kilicoglu and Bergler, 2009). In addition, if we consider the impact of novel findings there is also a need to take into account during the text-mining the temporal dimension (De Maio *et al.*, 2016).

Evaluation Techniques and Metrics

In literature many methods to evaluate text mining applications exist. In this section, an overview of the most common is presented.

The most used measures for evaluating information retrieval, document classification, NER, and other applications are:

- *Precision*, is the fraction of all retrieved documents that are labeled *relevant*

$$\text{Precision} = \frac{\#(\text{relevant items retrieved})}{\#(\text{retrieved items})} = P(\text{relevant}|\text{retrieved}) \quad (1)$$

- *Recall*, is the fraction of all *relevant* labeled documents that have been effectively retrieved

$$\text{Recall} = \frac{\#(\text{relevant items retrieved})}{\#(\text{relevant items})} = R(\text{retrieved}|\text{relevant}) \quad (2)$$

These measures can be clarified by examining the following so called Confusion or Error Matrix: (Table 5).

Then:

$$P = \frac{tp}{(tp + fp)} \quad R = \frac{tp}{(tp + fn)} \quad (3)$$

- *Balanced F-measure*, attempts to reduce precision and recall to a single measure.

$$F = 2 \frac{(PR)}{(P + R)} \quad (4)$$

- *Accuracy*, is the number of correct answers divided by the total number of answers. In terms of the Confusion Matrix above,

$$\text{Accuracy} = \frac{(tp + tn)}{(tp + fp + fn + tn)} \quad (5)$$

- *Error*, is the proportion of incorrectly identified instances:

$$\text{Error} = 1 - \text{Accuracy} \quad (6)$$

In addition, text summarization systems are usually evaluated by using ROUGE metric for estimating the similarity of the resulting summary with respect to a, so called, *gold summary* at syntactic level by matching the n-grams, or at semantic level (De Maio *et al.*, 2016) by evaluating *concepts* covered by the *generated summary*. There are several variants of ROUGE, the following one attains with the metric that estimates the number of n-grams that are both in the gold and in the generated summary:

$$\text{ROUGE} = \frac{\#(\text{relevant } n - \text{gram retrieved in Generate Summaries})}{\#(\text{relevant } n - \text{gram in Gold Summaries})} \quad (7)$$

Table 5 Confusion Matrix

	<i>Relevant</i>	<i>Not relevant</i>
Retrieved	True positives (tp)	False positives (fp)
Not Retrieved	False negatives (fn)	True negatives (tn)

Case Study: Text Mining for Simplifying Biomedical Literature Browsing

This section illustrates an example of text-mining techniques for enabling a biomedical literature-based application. This application was previously experimented in [De Maio et al. \(2015a\)](#) to extract multi-faceted data model enabling user-friendly browsing of biomedical literature. Then, it was extended to address natural language query processing in [De Maio et al. \(2015b\)](#).

The motivation essentially is to simplify the exploration of biomedical data occurring on the World Wide Web in unstructured biomedical repositories, e.g.: PubMed ([NCBI, 2013](#)) an open access full-text archive of biomedical literature, WikiGenes ([Hoffmann, 2008](#)) a global collaborative knowledge base for the life sciences data, and so on (see Relevant Website for PubMed and WikiGenes).

The proposed framework defines a methodology for categorizing biomedical literature acquired from PubMed by adopting concepts of biomedical ontologies as category names. The overall workflow is composed of the following phases:

- **Knowledge Extraction.** In this phase a common sense ontology is extracted, called *Unsupervised Ontology*, categorizing unstructured biomedical literature in unsupervised. It executes biomedical content wikification, that is the practice of representing a content with a set of Wikipedia entities (e.g., articles) ([Mihalcea and Csomai, 2007](#)), and consequently apply Fuzzy Formal Concept Analysis (FFCA) to extract ontology concepts that may be meaningful for the biomedical domain. A successive step filters out concepts that are meaningless by evaluating a matching degree with respect to a set of entities included in some *Biomedical Ontologies*.
- **Biomedical Ontologies Matching.** This phase implements a matching strategy to find relations between *Unsupervised Ontology* and existing *Biomedical Ontologies* concepts in order to support advanced queries and visualization procedures. In fact, concept matching methods let one organize and visualize collected biomedical resources, providing thus a navigation model based on ad-hoc faceted browsing visualizations. In particular, a friendly multi-facets visualization engine will be defined enabling integrated access to the biomedical data sources driven by existing biomedical ontologies.
- **Natural Language Query Processing.** This phase processes natural language queries by executing an ad-hoc matching algorithm that fires the most relevant concepts of *Biomedical Ontologies*. Then, the biomedical resources categorized in the fired concepts will be retrieved and ranked as the results of the incoming user's query. Analogously to biomedical content, this step performs the wikification of the input query, in order to capture the meaning in the user's request. Then, the match between the wikified query and the concepts of the *Biomedical Ontologies* is evaluated to carry out a ranked list of results.

The screenshot displays a web application titled "MULTI-FACETS VISUALIZATION" running on a local host. The interface is divided into several regions:

- Region A (Left Panel):** Contains three faceted ontologies:
 - Ontology of Genes and Genomes:** Includes filters for "protein-coding gene of Homo sapiens" (selected), "THRB (13)", "THRA (31)", "SRSF1 (6)", "SCN5A (13)", and "NEDD4L (31)".
 - PRotein Ontology:** Includes filters for "cellular_component" (selected), "Endosome membrane (3)", "plasma membrane (41)", "organism", "Brucella (11)", "Avena sativa (1)", "Gallus gallus (34)", and "Homo sapiens (7)".
 - Gene Ontology:** Includes filters for "cell component" (selected), "cell (74)", "cell junction (3)", "oxidoreductase complex (23)", "membrane", "Apical plasma membrane (91)", "coated membrane (51)", and "side of membrane (14)".
- Region B (Top Right):** Displays "Current Search Results" and a "Concept Facet" showing the selected path: "gene of Homo Sapiens > protein-coding gene of Homo sapiens" (selected).
- Region C (Bottom Right):** Shows "Results 6 of 31" with a list of search results, including:
 - "[Mutation process in the protein-coding genes of human mitochondrial genome in context of evolution of the genus]."
 - "[No authors listed] Mol Biol (Mosk). 2013 Nov-Dec;47(6):927-33. Russian. PMID: 25509854 [PubMed - in process] Related citations PubMed"
 - "Conserved syntenic clusters of protein coding genes are missing in birds. Lovell PV, Wirthlin M, Wilhelm L, Minx P, Lazar NH, Carbone L, Warren WC, Mello CV. Genome Biol. 2014 Dec 18;15(12):565. [Epub ahead of print] PMID: 25518852 [PubMed - as supplied by publisher] Related citations PubMed"
 - "ECM1 – extracellular matrix protein 1 Gene: ... mutations in the extracellular matrix protein 1 gene(ECM1). Although the precise function of ECM1... the radiation hybrid mapping of human ECM1 to 1q21, and the gene structure and coding sequence of human ECM1...Disease relevance of Related citations Wikigenes"

Fig. 4 Ontology Driven Faceted Individuals Browser.

We adopted some *Biomedical Ontologies* available in BioPortal, such as *Ontology of Genes and Genomes* – OGG, a formal ontology of genes and genomes of biological organisms; *PROtein Ontology* – PRO, an ontological representation of protein-related entities; *Gene Ontology* – GO (see Relevant Website for BioPortal, OGG, PRO and GO).

The resulting multi-faceted data model, simplifies the browsing by providing domain specific categories for accessing the literature. In general, the facet-based navigation (Yee *et al.*, 2003) is an efficient technique for navigating a collection of information based on incremental filtering. The goal of this data exploration technique, is to restrict the search space to a set of relevant resources. Unlike a simple traditional hierarchical category scheme, the users have the ability to drill down to concepts based on multiple dimensions. These dimensions are called facets and represent peculiar features of the information units. Each facet has multiple restriction filters and the user selects a value to constrain relevant items in the search space. Specifically, the multi-facets visualization engine proposed here provides a prototype directory web site which associates data (i.e., a biomedical resource) to biomedical ontologies' categories. The user interface is shown in Fig. 4: *Region A* shows the facets derived by different subtrees of concepts available in the selected biomedical ontologies; *Region B* illustrates the selected constraints specified by the user to filter the search space shown in *Region C*, and *Region C* shows the ranked list of the retrieved results according to the selection of specific facets values. For experimental results and more details about the case study illustrated in this section one can refer to De Maio *et al.* (2015a,b).

Conclusions and Future Challenges

The article provides an overview of the text-mining in Bioinformatics introducing fundamentals methods, literature-based applications, and existing solutions. In addition, a case study implemented for simplifying the biomedical literature browsing has been described.

The state of the art emphasizes that last trend of text-mining is related to the extraction of relation among entities considering also temporal aspects and impact of novel findings on the existing knowledge base.

Data-Information-Concept Continuum From a Text Mining Perspective

Danilo Cavaliere and Sabrina Senatore, Università degli Studi di Salerno, Fisciano, Italy

Vincenzo Loia, University of Salerno, Fisciano, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Nowadays, people communicate and share documents, opinions, ideas or anything they think or whatever happens to them in any moment of their lives.

Documents, posts, tweets, tutorials, etc., represent a substantial pool for unstructured data that need to be arranged to discover and retrieve relevant information as necessary.

The Web is indeed, the biggest existing source of information that still needs to be analysed in order to become accessible knowledge (Della Rocca *et al.*, 2017). In the era of big data, information mining is crucial to effectively access to potentially infinite, on-line knowledge, available from data-structured sources like Wikipedia but mainly from unstructured, natural language resources. There is an increasing need for analysing large amounts of texts in order to get the content meaning enclosed in them, not just as sequences of most frequent terms (whose comprehensive interpretation is left to the humans), but as a high-view synthesis of the content that represents conceptualization, feeling, opinions.

To this purpose, a complex data structuring, defined on discovered term relationships is required. The analysis of textual data is very tricky and needs an accurate processing to identify the relevant terms, their relationships, contextual information (i.e., surrounding text that can univocally characterize the meaning of such terms) to clearly recognize the conceptualizations. Many Concept Mining methodologies infer new concepts directly from the text. They generally employ syntactic and semantic relations among the most related terms or phrases to build contextual views, which are useful to extract and discriminate the concept. The complete process yields complex patterns in data to extract high level knowledge such as concepts, document topics, entities, feelings and behaviours.

This article presents an overview of the Concept Mining literature, discussing the main methodologies and the granularity level of the generated knowledge, i.e., the complexity in structuring the information adopted to define and express the concepts. Knowledge can be very basic involving simple information (individual terms), but it can also be more refined involving more articulated information (term-relationship structures). Generally, a lower-level knowledge is composed of elementary data, such as words and terms extracted from documents. Conversely, a higher-level knowledge, expressing more articulated information, is generally represented by more structured data.

The remainder of this article is structured as follows. Section A Layered Multi-Granule Knowledge Model introduces a new viewpoint of the knowledge representation, described by different granulation levels, according to the kind of knowledge modelled by Concept Mining approaches in the literature. Section Research Landscape presents an overview of the research landscape, focussing on the main research areas involved. Then, Section Approaches is devoted to introduce the main approaches in the Text Mining area, with a specific focus on concept-based approaches, classified according to their main information granule features: data, information, concept. Finally, based on the layer-based knowledge schema introduced in Section A Layered Multi-Granule Knowledge Model, Section A Schematic Description of a Multi-Layer Knowledge Representation introduces a granulation-based knowledge overview of the principal frameworks and tools, depicted through some knowledge structuring features, that are salient in the Concept Mining domain. Conclusion closes this article.

A Layered Multi-Granule Knowledge Model

The knowledge extraction is the complex activity of identifying valid and understandable patterns in data. These patterns are often related to the Natural Language Processing tools: the text content is parsed to identify topics that could be described by single terms, enhanced terms matching by adding phrases, complex key-phrases. Extracting the relations between terms, or verbs and their arguments in a sentence has the potential for identifying the context of terms within a sentence. The contextual information can be very informative for capturing the actual meaning of some terms, and the sense relations involved in the case of polysemy. The information about “who is doing what to whom” reveals the role of each term in a phrase and the higher level meaning of the phrase.

Simple terms or complex expressions represent different granularity levels of the knowledge that can vary depending on the formal methods used, the final conceptualizations and the intend meaning behind the sentences, whose interpretation often escapes automated machine-oriented approaches.

Fig. 1 shows our representation of the knowledge continuum, in an incremental layer-based transformation. The knowledge schema is composed of more granularity levels, starting from “atomic” entities, i.e., single words, to reach a high level representation of knowledge as ensemble of conceptualization and semantic correlations.

The lowest layer represents the primitive knowledge related to single words and terms in a document. Words collection per document is considered the basic data, or more simply, the *data*. The *Data* layer consists of raw data, which are generally composed by single words extracted from textual documents. These documents can be unstructured, i.e., the content is plain text, or structured, such as web resources with markup annotations (written in standard languages such as XML, HTML, CSS, etc.).

Fig. 1 Layered representation of the knowledge: from words to concepts.

In other words, the unstructured texts contain just words, while the structured ones contain meta-information like HTML tags, which can be used to extract more information about the concepts expressed by the text and the document structure. Let us consider the following document extract:

Canadian pop star Michael Buble married Argentine TV actress Luisana Lopilato in a civil ceremony on Thursday. The Grammy-winning singer of "Crazy Love" and his Argentine sweetheart posed for a mob of fans after tying the knot at a civil registry in downtown Buenos Aires.

Approaches modelling the *Data* layer directly work on the single words such as: "star", "actress", "TV", etc. and often only nouns (and adjectives in some cases) are processed: since these approaches work on the term frequency, proper nouns can be discarded if no named entity task is foreseen in the process. Usually, flat term ensembles are produced by this layer.

When data are furthermore processed or structured, the informative granule increases. The *Information* layer consists of more data structuring which considers linguistic and grammar relationships among atomic terms. More articulated sequences of words, often called keyphrases are extracted by the text analysis. Stemming, lemmatization, part of speech tagging are the basic NLP tasks involved; they allow the identification of terms that are linked by relations: sequences of only nouns, combinations of adjectives and nouns, named entities, etc. characterize the *information*.

By considering the previous extract, named entities such as "Michael Buble", "Buenos Aires", and a keyphrase such as "pop star", or syntactic relations between terms or entities, i.e., "civil ceremony" are the candidates to describe the information granule generated by this layer.

The highest layer of knowledge corresponds to a further and articulated structuring of the data which represent a more detailed and high-level knowledge. The informative granules of this layer define complex structure of terms that are supported by external sources, such as lexicons, knowledge bases and ontology-based schemas in order to provide a richer conceptualization, specialized thanks to contextual information and the term relationships. Compositions of simpler linguistic expressions yield complete and complex descriptions of concepts that, at this stage, are well-defined. The *Concept* Layer produces correlations of terms so rich that clearly identify a conceptualization, often specific in a given domain (according to the content of the processed document collection) and assumes a clear connotation for an authentic interpretation of the textual content. A crucial role is played by external knowledge-based sources, especially if they are semantically annotated, because, they yield additional (often inferred) information to extend, enrich and disambiguate concepts extracted by text. The extracted concepts, connected to each other by term-based relationships, compound a wider semantic network that represents the highest granulation layer.

The *Concept* layer can deduct more articulated concepts as facts from text; recalling the previous extract, the ex-novo concept <<marriage>> coming from the named entities "Michael Buble" and "Luisana Lopilato" could be extracted exploiting an ontological schema, thus enriching the initial more vague concept.

Each knowledge level introduces further relations among more articulated and high level data, which are taken into account. These relations are useful to provide a better contextual insight. To this purpose, let us consider a further example of knowledge stratification, given in Fig. 2, which considers the three words "code", "genetic" and "source". At the *Data* level, these words are considered, according to the proposed conceptualization, as simple three words or singleton terms <<code>>, <<genetic>>, <<source>> (see words beside the bullets at bottom of Fig. 2. Terms or words, at the *Information* level, are further structured according to term

Fig. 2 Knowledge stratification example.

relationships and/or other transformations (e.g. POS tagging)). Thus, terms appearing close to each other within a document can be recognized as named entities or linguistic period structures (e.g. nouns, verbs, etc.). In this case if the words “genetic” and “code” are very close and used as phrase subject or object, <<Genetic Code>> will be recognized as proper noun (see texts in rectangles, Fig. 2). Finally, these more structured data can be further structured at *Concept* level. At this level, the data include more contextual information about terms on different documents. So, the word “code”, at this level, could refer to distinct concepts according to relations with other terms in the text. If the term is considered as single word it represents a concept (<<Code>>), which refers to a general rule for converting a piece of information into another object or action. If the term is close to the term “genetic”, together they form a fundamental concept in biology which refers to the set of rules by which information on genetic material (RNA or DNA sequences) is translated into proteins. The term “code” could be related with other terms, such as “source”. In this case, the two words unambiguously refer to a key concept (<<Source Code>>) in Computer Science, it refers to the sequence of statements written in a human-readable programming language (see texts in the ellipses, Fig. 2).

In a nutshell, a strongly connected structure may be figured from the layer-based knowledge model shown in Fig. 1: all the informative granules are linked, through all the granulation levels, in order to generate a large knowledge base that comprehensively describes the entire text documents domain.

Related literature provided overviews and perspectives on Text and Concept Mining, particularly focusing on specific methodologies (e.g., classification (Brindha *et al.*, 2016)), semantics (Ilakiya *et al.*, 2012; Kathuria *et al.*, 2016; Saiyad *et al.*, 2016), specific applicative Text Mining tasks (e.g., document clustering (Saiyad *et al.*, 2016)), opinion mining (Khan *et al.*, 2009; Ambika and Rajan, 2016), information retrieval (Kathuria *et al.*, 2016). To the best of our knowledge there is no study evaluating Concept Mining approaches by analysing the knowledge they model. In fact, our main goal is to provide an overview of Concept Mining approaches analysed by a knowledge modelling perspective.

Research Landscape

Concept Mining Background

Concept Mining represents a subfield of Text Mining, aimed at extracting concepts from text. Concept Mining approaches are largely used in many fields like Information Retrieval (IR) (Joel and Fagan, 1989) and Natural Language Processing (NLP)

(Cambria and White, 2014). The main applications include detecting indexing similar documents in large corpora, as well as clustering document by topic.

Most of the common techniques in this area are mainly based on the statistical analysis of term frequency, to capture the relevance of a term within a document (Yang *et al.*, 2014). More accurate methods need to capture the semantics beyond the terms.

Traditionally concept extraction methods employed thesauri like WordNet [WordNet], which transform words extracted from document in concepts. The main issue related to thesauri is that the word mapping to concepts is often ambiguous. Ambiguous terms can be generally related to more than one concept, only the human abilities allow contextualizing terms and find the right concept to which terms belong. Since thesauri do not describe the context along with the terms, further techniques have been introduced to face the word sense disambiguation; some of them perform linguistic analysis of text, based on term frequency similarity measures, some others employ knowledge-based models to generate a context useful to evaluate a semantic similarity between concepts.

Since documents are often described as a sequence of terms, a widely used data representation adopted by many methods is the vector space model (VSM) (Aas and Eikvil, 1999; Salton *et al.*, 1975; Salton and McGill, 1986). The VSM model represents each document as a feature vector of terms (words and/or phrases) present in the document. The vector usually contains weights of the document terms, defined mainly on the frequency with which the term appears in the document. Other techniques extend the VSM representation with context-related information for each term, transforming the VSM vector in a global text context vector. This way, a global context about a term is built by merging its local contexts, which are derived from each document where the term appears in Kalogeratos and Likas (2012).

Document similarity is evaluated by considering the similarity between their corresponding feature vectors. Well known similarity measures are euclidean, cosine, Jaccard, etc. Other techniques use document attribute information to extract inter-document information to calculate their similarity (Tombros and van Rijsbergen, 2004).

In Text Mining domain, the term importance in a document is based on the frequency with which the term appears in the document. But a high frequency does not mean that a term contributes more to the meaning of a sentence. There are some words with a low frequency which provide key concepts to the sentence. The importance of the term is also evident in summarization activities (Liu *et al.*, 2009). The sentence meaning depends strongly by verbs and their arguments. Verb analysis allows finding out who is doing something, or acting toward something or someone else, clarifying the role of each term in the sentence.

Whether extracting sophisticated information or simple ones, these techniques constitute the underlying methodological background of the Concept Mining research area and most approaches are modelled and developed on the basis of them.

Beyond the Knowledge: Connections and Relations Among the Main Research Domains

As the amount of available web resources continues to increase, the need of knowledge structuring is becoming predominant to enhance many activities, such as document categorization, indexing, web search. Structuring the knowledge means eliciting a structure informative (conceptualization), which connects the atomic elements (often linguistic terms that are relevant within a given collection) through reciprocal relations. Text Mining techniques are the methodological underpinnings on which the semantic infrastructure can be built to translate natural language text into concepts, and then into knowledge.

There are a lot of research domains that strictly affect and conversely are affected by the Text Mining issues. Our review inspects three different even though interrelated research streams, which are mostly involved in Text Mining tasks, to improve the access to unstructured data and alleviate the knowledge discovering. Fig. 3 shows the involved macro-areas: Natural Language Processing (NLP), Semantic Web (SW) and Artificial Intelligence, and Information Retrieval (IR) and their more specific sub-fields. Next sections will provide a brief overview of each research domain introducing the main characterizing approaches.

Natural language processing

Natural Language Processing (NLP) involves basic tasks in Text Mining activities, especially if they are targeted at concept extraction. One of the research goal in NLP is to generate computational models that simulate human linguistic abilities (reading, writing, listening and speaking). NLP aspects distinguish in low-level activities, such as tokenization and stemming of terms, shallow syntactic parsers to extract meaningful terms and term frequency index calculation; and more articulated activities, such as the utilization of a lexical resource (thesaurus) to support the word sense disambiguation (Navigli, 2009) or building ontology-based knowledge bases for topic extraction.

Modern approaches to NLP involve supervised and unsupervised methods from machine learning area, such as clustering, support vector machine (SVM) and undirected graphical models or decision trees.

The ultimate goal is to guarantee clear understanding of the word meaning, word role (i.e., sense) in the sentences, in order to correctly interpret the embedded semantics, associate the contextual information and finally elicit concept-targeted term relationship.

NLP tasks also contribute to build semantic networks (also known as conceptual graphs) that reveal correlations between terms (Kozareva and Hovy, 2010), and the text summarization (Erkan and Radev, 2004). Term relationships are inspected to support NLP applications, as well as to define domain models: graph models build semantic knowledge extracting term relationships, by analysing grammatical relations such as co-occurrence of noun (Widdows *et al.*, 2002). Standard NLP systems employ parsing methods in order to build and analyze the sentence structure. Traditional parsing methods focus on finding tree-based structures, capable of representing grammatical rules, in order to represent the syntax of phrases and clauses of a set of words in a document.

Fig. 3 Text Mining and the main correlated fields.

Therefore, words are tagged and related according to their role in a sentence (e.g., noun, verb, adjective, etc.) even though this activity can generate more and ambiguous syntactical schemas of the same sentence.

In order to reduce ambiguities, a traditional solution produces selectional restrictions, which are hand-coded syntactic constraints and preference rules on words, generally defined by human experts. These constraints restrict the general usage of the word in a sentence, identifying the correct sense. As an example of selectional restriction on a word, let us consider the word “play”, restrictions may be defined according to the terms the verb “play” appears with (e.g., “play guitar”, “play a role”), or on its meaning in the sentence as noun (“It’s your play”). The problem with selectional restrictions is that they are time-consuming, when ad-hoc defined by humans. Moreover, selectional restrictions are often not exhaustive and so they miss a lot of metaphorical and context-specific meanings. To address this issue, the current solutions use statistical or knowledge-based methods to learn automatically syntactical and structural preferences directly from text corpora. These methods produce a term relationship-based context on terms and sentences exploring the surrounding information and producing a better disambiguation. The rationale behind these methods is that the relationship between words, whose aim is to find which words group each other, can add information useful to learn semantic relationships among terms, and discover the word meaning in a sentence.

Besides the word sense disambiguation, another important NLP activity is the named-entity recognition (NER). It is traditionally based on linguistic grammar techniques as well as statistical models (Finkel *et al.*, 2005), aimed at discovering named entities in text.

With the advent of Semantic Web technologies, some projects enhanced named entity recognition with semantics; for instance, FOX [FOX] is an open-source framework that implements RESTful web services for providing users with disambiguated and linked named entities coded in RDF-based serialization formats.

Gate [Gate] is a text processing framework which combines data-driven (words that describe concepts) and knowledge-driven (relations that link concepts) approaches in order to find a link with Semantic Web approaches.

SHELDON (Recupero *et al.*, 2015) represents indeed a clear example of a NLP and SW hybridization tool, by implementing several machine reading tasks to extract meta-data from the text. It exploits a tool for automatically producing coded ontologies and linked data from text, adopting Ontology Design Patterns and Linked Data principles, relation extraction, frame detection, automatic typing of entities and the automatic labeling functions (Presutti *et al.*, 2012).

Semantic web

The proliferation of textual information makes the extraction and collection of relevant information a tricky task. Although search engines are recently enhanced with Artificial Intelligence techniques, the vagueness of natural language is still an open problem. At present, the ontology has proven itself to be an effective technology for representing as a form of concepts, the web information and then sharing common conceptualizations that are referenced as knowledge.

An ontology gathers concepts from the real world by means of unambiguous and concise coding. At the same time, it should capture the terminological knowledge that sometimes embeds imprecise information, should support the management of semantic data and the intrinsic ambiguity in their model theoretic representation, provide enhanced data processing and reasoning, and then supply a suitable conceptualization that bridges the gap between flexible human understanding and hard machine-processing (De Maio *et al.*, 2014). Simple ontology schemas, called taxonomies reflect vocabulary properties (such as term definitions, constraints and relationships) are often used as semantic models representing hierarchical classification of concepts. A taxonomy describes relations between related concepts as super-sub category or subsumption relationship. This schema enables to represent articulated concepts as subsets of more simple concepts, and create a layered structure based on concept complexity useful for concept analysis. In most cases, taxonomies are represented by hierarchical tree structure of classifications for a given set of objects. In order to represent concepts, an ontology can be seen as a semantic network composed of nodes and edges to link nodes, where the nodes represent the concepts and the edges represent the relationships among concepts.

Abstract concepts are defined as ontology classes, while a real concrete example of an abstract concept is represented by class instance (or individuals). The relations among two different concepts are characterized by ontological properties. Ontological axioms are represented in the form of triples subject-predicate-object, in order to represent that a resource (subject) has a property (predicate) which assumes as value another resource or a literal (object). The model-theoretic semantics behind the Semantic Web are based on Description Logics (DLs), in order to model assertions and perform reasoning on the ontological schema, which produces new axioms and increase the knowledge about the concepts.

Coding (meta-) data and relations between them into an ontology, starting from unstructured text is a necessary step towards the knowledge modelling (Navigli and Velardi, 2008). Ontologies and ontology-based applications (Navigli *et al.*, 2004) achieve language processing for extracting keywords inherent to domain concepts from natural language documents.

Semantic Web technologies yield knowledge in the form of concepts and relations among them; they translate the vagueness of natural language (embedded in the linguistic terms) by identifying conceptual entities in the resource content. Intelligent AI computing proactively supports these activities, modelling this ambiguity by more suitable methods and techniques that natively reflect the uncertainty and the reasoning of the human thought process (De Maio *et al.*, 2014).

The nature of the ontology modelling moves towards a shared conceptualization and a consequent reuse of the same data, reinforcing the request that data about concepts and their relationships must be specified explicitly and data needs a robust formalization. Due to the stringent reliance of applications on well-designed data structure, semi-automatic tools like OntoLearn [OntoLearn], AlchemyAPI [AlchemyAPI], Karlsruhe Ontology (KAON) framework [KAON], Open Calais [Open-Calais] and Semantria [Semantria] are widely developed, to automatically extract entities, keywords and concepts from unstructured texts.

Systems and applications as KnowItAll (Fader *et al.*, 2011), DBpedia (Auer *et al.*, 2007), Freebase (Bollacker *et al.*, 2008) also provide publicly semantically annotated knowledge resources; some others such as ConceptNet (Speer and Havasi, 2012), Yago (Suchanek *et al.*, 2007) aim at conceptually capturing common sense knowledge; sometimes, due to the quality bottleneck, projects like Cyc, OpenCyc (Matuszek *et al.*, 2006) and WordNet are often built on manually compiled knowledge collection.

Information retrieval

The query-based paradigm has a long and predominant tradition in Information Retrieval, whose main focus is the study to support users in retrieving information, that match their description. The user submits the query (that represents the information need) to the IR system, generally through a user interface, composed of a text entry box by which the user can type his/her requests in string format. The information item collection is a corpus of documents. Generally, this information depends by the selected engine: if the IR system deals with a web engine, the corpus may be provided by a web crawler. Otherwise in desktop search applications, the document collection is generally gathered from a hard drive.

A typical IR workflow is composed by some specific tasks, whose final output is a ranked list of information sources. The main tasks are as follows:

1. *Document indexing*: is a typical structure adopted by desktop and web search engine in order to speed up the search over large corpora. The structure is defined on an indexing of the textual contents.
2. *Query formulation*: once the document indexing is completed, user search query is also processed. Firstly, the query is parsed and then some transformations (extensions, refinements) are applied to the data in order to get a system representation of the user need.
3. *Query-Documents Matching*: the query is matched with terms composing the document representation, to find relevant documents that meet the user needs. The matching method is built according to a defined retrieval model.
4. *Result Ranking*: a ranked list of relevant documents is returned to the user. The ordering of this list is guaranteed by a ranking algorithm, which assigns a matching score to each document, from the most to the less relevant. The objective is to return those documents that meet the user need.

The effective understanding of user query needs the identification of relevant query terms and their term relationships. The importance of term in a document or in the whole corpus is generally estimated by a term weighting factor, often, expressed by frequency-based measures. The most used measures are indeed the term frequency (tf) and the term frequency/inverse document frequency (tf/idf); other measures involve probability and information theory, i.e., the mutual information which measures the mutual dependence between the two variables (terms).

A term relationship evaluation may involve the importance of the term (e.g., term weighting factor), as well as syntactical and semantic relations. Among them, grammatical relationships, such as synonym, hyponym, etc., have gained an increasing interest in IR area, because they can be used to better distinguish words for query expansion, and for calculate relevancy score of a document for a given query (Snow *et al.*, 2006; Giuliano *et al.*, 2007). These techniques are often based on term clustering, targeted at word sense disambiguation (Phillips, 1985; Schütze, 1998).

In the recent years, the IR process is becoming more interactive and dynamic, customized to the user preferences. Generally short-term queries personalization depends on recent searches and feedback provided by user, who pinpoints the document he/she finds most interesting. Therefore, feedbacks and recent activities are used to refine the result, generally, performed by a query reformulation. IR systems are increasingly oriented to the user personalization, taking into account the user navigation (visited sites, recurring web search, etc.), habits and preferences (Case, 2012; Golovchinsky *et al.*, 2009; Marchionini and White, 2009); also investigating on knowledge structures to support dynamic user queries (Ben-Yitzhak *et al.*, 2008).

Contextualized collected information assume a crucial role to the user profiling; to this purpose, Semantic Web technologies have been investigated to model human behaviours.

Semantic Web provides semantically enriched standards to provide a meta-data description of web resources. It provides a knowledge infrastructure to represent concepts and relations between concepts, sharable by humans by especially by machines, in a way that is cost-effective and consistent with adopted models and ontology schemas. Although there is a plethora of ontologies disseminated on the Web, they are often too general or specialized, sometimes covering only a portion of the domain of interest. At the same time, developing an ontology from scratch is a time-consuming, labor-intensive task that requires a deep understanding of the domain vocabulary (De Maio *et al.*, 2014). For this reason, IR community showed interest in automatically generated domain models from texts, which guarantee language independence. Some studies (Lau *et al.*, 2008; Kruschwitz, 2003; Sanderson and Croft, 1999) have yet propose some new approaches using these techniques for query expansion, suggestions, filtering information, etc.

Data-driven approaches as well as concept-driven approaches are mostly proposed in the IR approaches, even though several studies achieve, which build ontological model to capture domain knowledge for query expansion, some others extract semantic relationships from text to modify query (Clark *et al.*, 2012).

Approaches

According to the knowledge stratification model introduced in Section Introduction, Text Mining approaches have been organized in three granularity-based categories: data, information and concept driven, ranging from the lowest granulation level, the data, then to reach the highest one, the concepts whose ensembles compound the whole knowledge.

Data-driven approaches work on low-level data, i.e., raw data that need to be processed to extract atomic terms, verbs or key-phrases from the text. In these approaches linguistic regularities, such as term co-occurrences, term ensembles are automatically identified, generally with no human intervention. Relationships are indeed extracted in automatic way, through statistical or cluster-based methods that find correlation between term couples and term ensemble. These relations are often of different nature, specificity, type, sometimes based on grammatical dependencies, but in general they are flat, without any type of structuring.

Information-driven approaches work on slightly more complex data structures, that can include linguistic expressions composed of more than one term, named entities, key-phrases.

At this granularity level, discovered relationships aim at identifying higher level data, that can be considered embryonic conceptualizations. Sentence analysis techniques are widely inspected, especially part-whole relations and Part-of-speech (POS) relations, that support the knowledge structure. Unlike data-driven models, information-driven approaches are supported by supervised methodologies, sometimes exploiting external sources.

Concept-driven approaches instead, work on more specific types of relationship. Generally, these approaches extract lexical relationships like synonyms, hyponyms, etc. between (complex) terms, in order to extract concepts or topics expressing a conceptualization. Relationship types are a-prior defined, exploiting a thesaurus or dictionary such as WordNet, FrameNet which collect grammar relationships. Supervised learning methods use several levels of syntactic information, with more control over the identified relationship, which generally provide a deeper knowledge structuring about the concepts. Knowledge structures are often hierarchies of concepts at different levels, ranging from a very specificity to a high-level generalization. At the same time, the knowledge may lack of some specific notions related to the raw data (e.g. words), which could badly affect the adaptability of the system to specialized domains.

Some approaches included and classified according to the three granularity-based layers are described in the next sections.

Data-Driven Approaches

Data-driven approaches can be divided in three main categories: unsupervised, semi-supervised and supervised methods. Unsupervised methods do not need human annotation in the training phase even though some difficulties arise in producing annotation of explicit classes and relationships. As a consequence, the unsupervised methods need time-consuming training annotation tasks, even though the resulting annotations can be high quality and very specific data in the reference domain.

Semi-supervised methods reduce the amount of human effort for the annotation: these methods generally use unsupervised learning but need a human intervention to guarantee some minimal control on the data processing. Data-driven approaches usually exploit unsupervised methods, that basically work on raw data, and take the unstructured text (natural language documents, query logs, etc.) as input. In order to identify relevant terms, frequency analysis is usually used in text processing, coupled with statistical techniques that elicit term co-occurrences in the text, targeted at discovering term relationships in order to identify richer terms (Lauren and Doyle, 1961).

Co-occurrence analysis (Phillips, 1985) indeed, supports the building of conceptual networks and syntagmatic lexical networks to build phrasal patterns, useful to extract and cluster document words according to their vocabulary sense definitions. In Schütze (1998) words and their co-occurrence are mapped on a high dimensional space and clustered with the Expectation-Maximization (EM) clustering algorithm, initialized by group average agglomerative clustering on a sample. Other studies focus instead, on extracting hierarchical terms relationship built on subsumption relations between concepts, represented by the terms extracted from retrieved documents (Sanderson and Croft, 1999).

Most of these approaches extract “concepts” from textual collection, which generally are words, compound terms or term ensembles co-occurring in the documents. These approaches are based on typical NLP tasks such as stop-word removal, stemming, part-of-speech tagging, and then coupled with linguistic patterns selection and statistical analysis (Lau et al., 2007; Sanderson and Croft, 1999), supported by measures such as frequency, (balanced) mutual information, especially to select the domain concepts.

The vagueness of natural languages need more suitable methods and techniques that natively reflect the uncertainty and (fuzzy) reasoning of the human thought process. Fuzzy Logic is remarkably a simple way to process vague, ambiguous information, expressed in the natural language text. Fuzzy subsumption relations derived from term associations delineate hierarchical structures (Sanderson and Croft, 1999), semi-supervised fuzzy clustering methods return the special term ensembles, that are tuned with user suggestions on documents similarity (Loia et al., 2003).

A multi-view analysis of data is described in Loia et al. (2007), where a collaborative fuzzy clustering is applied on two different feature spaces extracted by the same dataset: one feature space is a more traditional, generated by the word frequency in the text, while the other space is built considering the mark-ups in the page; specifically, the semantic tags from the RDF [RDF] language appearing in the tagged documents.

Some other approaches work on structured text. Tags of the markup languages, such as HTML, XHTML, XML, etc., aim at capturing document structure to extract useful row information (Kruschwitz, 2003; Brunzel, 2008). Most data-driven approaches use clustering techniques to find term correlations that come from the document collection.

Agglomerative clustering (Chuang and Chien, 2005) for instance, produces hierarchical trees of term clusters; fuzzy clustering techniques (Loia et al., 2003, 2007) group the terms saving the fuzziness of the linguistic terms, and provide a membership degree to each generated concept-cluster.

Some approaches work on some special data, such as search log files, click data, etc. in order to extract concepts from user behaviour and collected profile (Baeza-Yates, 2007; Baeza-Yates and Tiberi, 2007; Boldi et al., 2008); techniques including both queries and URLs are also inspected: in Deng et al. (2009), Craswell and Szummer (2007), bipartite graphs are modelled starting by these data sources to find the related terminologies in documents. Some studies also focus on search links, especially the analysis of clicked links rather than the not clicked ones (Radlinski and Joachims, 2005).

Information-Driven Approaches

According to Fig. 1, the *Information* layer is composed of more complex data structures that come from the entities in the *Data* layer.

Information-driven approaches are mainly based on supervised approaches, targeted at extracting entity relationships for the concept extraction. Supervised methods usually require a training phase: syntactic and lexical aspects form the feature space to feed a learning algorithm, which classifies on the basis of a pre-annotated collection of relations between terms, named entities and

concepts. Several supervised methods are employed for Concept Mining (Brindha *et al.*, 2016) such as k-nearest neighbour, support vector machine, decision tree, etc. These methods are widely used by information-driven approaches because they work on a mid-level of syntactic data including part-of-speech (POS) tagging and named entities recognition.

A classification algorithm presented in Girju *et al.* (2006) recognizes true part-whole relations in text. This approach firstly retrieves candidate relationships from text, then the learning algorithm discovers the true relationships.

Some other methods extend pre-existing syntactic schemas. The algorithm proposed in Snow *et al.* (2006) incorporates the evidence from multiple classifiers over heterogeneous relationships to optimise a pre-existing taxonomy. Some studies (Reichartz *et al.*, 2009) present novel approaches based on the tree kernel method to extract association patterns, exploiting the complementary knowledge taken from grammar parse tree and dependency parse tree.

Other research focuses on kernel models to discover relations between named entities: in (Giuliano *et al.*, 2007), entity relations, WordNet synsets and hypernyms have been modelled as kernel functions, in order to extract relations among named entities.

Some other information-driven approaches adopt unsupervised methods. In particular, among the most common applications of these methods, there is document clustering, whose main aims are to extract topics and provide filtering on documents. Information-driven approaches perform document clustering employing named entities to capture document semantics, such as a presented fuzzy document clustering built on named entities (Cao *et al.*, 2008). Another approach prefers named entities to keywords for the definition of a vector space model, which is built on entity names, name-type pairs and identifiers. Then, the model generated is used to evaluate document similarity and perform hierarchical fuzzy clustering. In (Sinoara *et al.*, 2014) several experiments have demonstrated that hierarchical clustering based on named entities, as privileged information, gets better cluster quality and interpretation.

Semi-supervised methods are potentially very effective; a document clustering and classification is presented in Diaz-Valenzuela *et al.* (2016), where an automatic generation of the supervision is computed by the analysis of the data structure itself. The analysis is based on a partitional clustering algorithm that, discovering relationships between pairs of instances, has been used as a semi-supervision in the clustering process.

The approach described in Mintz *et al.* (2009) builds a hybrid framework to extract relations between named entities. This approach combines supervised and unsupervised methods, extracting relations from the semantic database Freebase [Freesbee] with the aim of providing supervision. All the sentences containing each pair of extracted entities, involved in relation, are retrieved in order to extract textual features to train a relation classifier.

As for automatic supervision, direct feedback from humans may also improve concept learning, especially in the IR field: a proposed agent-based framework provides support to user's web navigation, suggesting new web pages related to his/her previous searches. This framework retrieves similar pages to the ones visited by the user, who chooses his/her favourites, these remarks are transformed in semantic evaluations which are provided to a clustering algorithm aimed at extracting topics. Then term frequency or thesaurus-based techniques are employed to discover new terms useful to find new pages fitting user interests (Loia *et al.*, 2006).

Concept-Driven Approaches

Concept-driven models focus on building more refined data, expressing articulated concepts. They represent the upper layer of our abstract model described in Fig. 1.

These approaches generally achieve models, integrating the data, from local collections or sources with external knowledge sources, such as WordNet, Wikipedia, etc., in order to provide a complete and enriched domain knowledge model.

Domain model building is generally supported by using external tools. These tools are historically employed to extend lexicons with semantic relations, as well as to solve word-sense ambiguity and recognize right term meanings. Most of these tools are freely available, large-scale and provide high-quality data. Many methods require these tools to build knowledge bases on the domain (e.g., DBpedia, Yago), accomplish some specific tasks (e.g., word-sense disambiguation), perform linguistic and sentiment analysis (e.g., AlchemyAPI, WordNet) etc. One of the most used tools is WordNet, which is a lexical database providing knowledge about lexical features of text. Its capability of finding similar meaning words and put them in synonym groups (synsets) is widely used for disambiguation. Some studies have proposed methods to extend WordNet with further knowledge: sets of related words (topic signature) for topic discovery (Agirre *et al.*, 2000); further vocabulary, such as Longman dictionary of contemporary English [Longman]; ontology-based sentiment and emotion representation (Brença *et al.*, 2015); extension of complex concepts with relative descendants (e.g., restaurant for bistro, cybercafe) (Navigli, 2005).

Although the most of concept-driven methods focus on exploiting external sources, some solutions aim at enhancing the domain knowledge. The goal is to find how to enrich domain knowledge with new information and how new information can be included in the high-level knowledge representation. Some studies concentrate on searching a specific criterion to insert new information in the knowledge: the approach provided in Chen *et al.* (2008) evaluates the term distance from concept groups to map a new term within a concept. In this work, the Latent Semantic Analysis (LSA) technique is employed to strengthen the semantic characteristic of keywords and transform the term-document matrix into a high dimensional space based on collected web pages. Another latent model is Latent Dirichlet allocation (LDA), which is a generative statistical model for collection of discrete data, where each item of the collection is modelled as a finite mixture over an underlying set of topics. A document retrieval system has been built in Della Rocca *et al.* (2017), by exploiting both the latent models; it describes each document as an

ontology based network of concepts. In particular, this system adopts LDA model to extract topics from documents producing a granular knowledge on three levels (document, topic, word), enriched with semantic relations from WordNet and WordNet Domain [WordNet domain]. LSA provides instead a spatial distribution of the input documents, which allows to retrieve the most relevant documents and the correlated network of related topics and concepts.

Another formal framework used for the concept layer is Formal Concept Analysis (FCA). It supplies a basis for conceptual data analysis and knowledge processing. It enables the representation of the relationships between objects and attributes in a given domain. In the Text Mining domain, documents could be considered object-like and terms considered attribute-like (Cimiano *et al.*, 2005). FCA produces a one-to-one relationship between groups of similar concepts and a set of attributes, producing partially ordered relationships, like subsumption relation, between similar groups of concepts.

FCA has been used to produce formal ontologies, in fact many knowledge-based approaches employ FCA to produce high-level representations to model terms, concepts and their relationships; some fuzzy extension of FCA are proposed in (De Maio *et al.*, 2012) to build an ontology useful for web document view and organization. In (De Maio *et al.*, 2014), FCA has been flanked by the Relational Formal Context (RCA) with the purpose to automatically build an ex-novo ontology useful for semantic annotation of web pages.

Due to the nature of written languages, Fuzzy Logic has been used also for sentiment analysis and emotion detection. A framework for sentiment and emotion extraction from web resources has been introduced in Loia and Senatore (2014): it employs fuzzy sets to model sentiments and emotions extracted from text. The intensity of emotions, expressed according to Minsky's conception of emotions (Marvin, 2007), has been tuned by fuzzy modifiers, which act on the linguistic patterns recognized in the sentences.

Some other studies focus on ontology learning and enrichment. Ontolearn (Navigli *et al.*, 2004) for instance, is a framework capable of automatically generating an ontology, or extending a pre-existent schema, using external resources (e.g., dictionaries, thesauri), such as WordNet. Extending a pre-existing schema can be a non-trivial task, in fact an analysed framework enriches a core ontology with external glossary about named entities, such as WordNet and Dmoz taxonomy (Navigli and Velardi, 2006). Another study proposes a semi-automated model which uses a starting ontology, whose instances and lexicalizations are used to extract new candidates, in order to enhance the ontology knowledge (Valarakos *et al.*, 2004). Ontology learning is employed to reduce human involvement.

In order to discover new meaningful term and concept relations researchers have inspected inference methods, which enable to enhance the knowledge base about the term and concept context with new facts about term relationships. Artequkat (Alani *et al.*, 2003) is a framework able to extract knowledge from web, store knowledge and produce artist biographies. Artequkat extracts knowledge from web pages by some syntactic and semantic analyses and employs Gate and WordNet to enrich an a priori defined ontology which is stored. Then the biography generator can query the knowledge base by using an inference engine.

Some other studies present new high-level structures, other than ontologies, to represent and model high-level knowledge about terms, such as graphs or automata. An example is provided in Shehata *et al.* (2013), proposing a concept-based retrieval model which employs the conceptual ontological graph (COG) representation to capture semantic features of the term, such that each term is ranked according to its contribution to the meaning of the sentence. The top ranked concepts are chosen to build a concept-based document index for text retrieval.

A Schematic Description of a Multi-Layer Knowledge Representation

In the light of the layered stratification of the knowledge, described in Section A Layered Multi-Granule Knowledge Model, the main frameworks and tools presented across this article will be further analysed and classified, according to the given layered knowledge model. To this purpose, some salient features/aspects have been selected to evidence peculiarity and/or similarity in the basic approaches, at each knowledge layer.

Tables 1–3 show indeed the main frameworks, whose methodologies and implementation design produce a knowledge model that better reflects a knowledge layer of Fig. 1. The selected features are mainly five, described as follows.

1. Research sub-field: this feature identifies the research areas where the framework and tools are located, according to the methodologies, functionalities and techniques employed. The feature highlights the synergies between the different areas involved in the knowledge structuring, through an incremental informative granulation that yields the knowledge representation.
2. Knowledge representation: reports formal methods used for the knowledge extraction from text. It presents the methodologies and the technologies employed to represent and model the knowledge extracted.
3. Ontology-based support: evidences the role of external ontologies or ontology-based tools, in supporting the concept-based knowledge representation. Referencing to concepts of existing ontologies to describe entities is becoming a common practice in Text Mining.
4. Similarity measure: presents a primary feature, aimed at discovering low-level informative granules of knowledge. The similarity is the basic measure to compare text entities, such as words, terms, named entities, concepts, targeted at discovering syntactic or semantic relationships. Syntactic similarity concerns the sentence structure, exploiting for instance, the root or the lemma of a term; the semantic similarity is more complex to elicit: it discerns the correct sense (or concept) behind the term (or sentences) to get the contextual, actual meaning.

Table 1 Data-driven approaches test results

<i>Approach</i>	<i>Research sub-fields</i>	<i>Knowledge representation</i>	<i>Ontology-based support</i>	<i>Similarity measure</i>	<i>Semantic annotation support</i>
Phillips (1985)	NLP, clustering conceptual maps	Syntagmatic lexical networks	n.a.	Co-occurrence similarity	No
Schütze (1998)	IR, EM clustering	Word space model	n.a.	Semantic similarity	No
Sanderson and Croft (1999)	IR, subsumption relation	Subsumption relation-based hierarchy	n.a.	Semantic similarity	No
Loia <i>et al.</i> (2003)	SW, P-FCM	Word space model	n.a.	Proximity measure	Yes
Loia <i>et al.</i> (2007)	SW, P-FCM, Collaborative clustering	Word and RDF-tag space model	n.a.	Proximity measure	Yes
Lau <i>et al.</i> (2007)	NLP, POS tagging	Fuzzy subsumption relation hierarchy	n.a.	Term frequency, mutual information	No
Kruschwitz (2003)	IR	HTML tag structure	n.a.	Semantic similarity	No
Chuang and Chien (2005)	IR, agglomerative clustering	Suffix hierarchy	n.a.	Topological measure	No
Baeza-Yates (2007)	IR, graph theory	graph-based relations	n.a.	Semantic measure	No

Table 2 Information-driven approaches test results

<i>Approach</i>	<i>Research sub-fields</i>	<i>Knowledge representation</i>	<i>Ontology-based support</i>	<i>Similarity measure</i>	<i>Semantic annotation support</i>
Girju <i>et al.</i> (2006)	IR classification rule extraction	Part-whole relations	n.a.	Topological similarity	No
Snow <i>et al.</i> (2006)	IR classification	Hyponymy hypernymy	WordNet	Taxonomy	Yes
Reichartz <i>et al.</i> (2009)	IR, kernel methods	Parse tree	n.a.	Phrase similarity	No
Giuliano <i>et al.</i> (2007)	IR, kernel methods	Entity relations (Synsets, Hypernym)	WordNet	Semantic similarity, WordNet synsets	Yes
Cao <i>et al.</i> (2008)	IR, hierarchical fuzzy clustering	Fuzzy vector space model	n.a.	Fuzzy similarity measure	No
Diaz-Valenzuela <i>et al.</i> (2016)	IR, document clustering partitionial clustering	Clustering-based constraints	n.a.	Frequency measure	No
Mintz <i>et al.</i> (2009)	IR relation extraction classification	Free base relations	Freebase	Entity-relation model	Yes
Loia <i>et al.</i> (2006)	IR, topic extraction proximity-based fuzzy clustering	Fuzzy multiset	n.a.	Fuzzy measure	Yes

5. Semantic annotation support: semantic annotation is a new way to represent knowledge in the form of concepts, which is far from the textual annotations on the content of documents. The feature indicates if the annotation is retrieved by pre-existent or ad-hoc defined ontologies. Tools that achieve IR tasks using semantic web technologies often carry out annotation tasks.

These features are shown in **Tables 1–3** with respect to the main frameworks, tools, presented in the article, and classified according to the three knowledge layers.

As shown in **Table 1**, data-driven approaches work on low-level data. These approaches mainly adopt linguistic, statistical and unsupervised methods, such as clustering, word-space model and subsumption relations. The knowledge representation is strongly based on term-to-term relationship, often generating flat ensemble of terms. In some cases, other formal methods, such as Formal Concept Analysis (FCA), fuzzy set or graph theory, are also used, that produce a kind of term structuring. Data-driven approaches do not exploit semantic annotation or require external ontology-based tool support. Although the work presented in Loia *et al.* (2007) may seem an exception, it is a tentative to combine two different data spaces extracting from the same dataset, but describing terms and (semantic-oriented) RDF-tags, in order to mix the data with different a feature nature, in the clustering generation.

Table 2 shows information-driven approaches that usually extract relations between keywords or (more complex key-phrases) named entities adopting supervised or semi-supervised methods. The enhancement with respect to previous layer is that these approaches exploit topological representations for row data extracted from text. Formal models such as fuzzy set, part-whole

Table 3 Concept-driven approaches test results

<i>Approach</i>	<i>Research sub-fields</i>	<i>Knowledge representation</i>	<i>Ontology-based support</i>	<i>Similarity measure</i>	<i>Semantic annotation support</i>
Della Rocca <i>et al.</i> (2017)	IR, conceptual analysis	LDA-based concept learning	SKOS, WordNet	Statistical (LSA)	Yes
Cimiano <i>et al.</i> (2005)	IR, formal concept analysis (FCA)	FCA-based hierarchy	n.a.	Frequency measure, topological measure	No

Agirre <i>et al.</i> (2000)	NLP, word-sense disambiguation	Topic signature WordNet concepts	WordNet	Topological similarity	No

relations, entity relations induct richer, semantic relations between named entities. The revealed tendency is to find patterns useful to group named entities and keywords, and clustering methods are largely used in order to fulfil this task. Some approaches gather additional information from external tools, such as thesauri and knowledge bases, in order to better identify the term sense and then produce more meaningful relations among NE and keywords. [Table 2](#) highlights that information-driven approaches are mainly used in Information Retrieval field.

Concept-driven approaches shown in [Table 3](#) are aimed at producing a more refined representation of the corpus in input, achieving a knowledge structuring that evidences a deeper granularity of the information. These approaches focus mainly on building a conceptual map or term-dependency network that allow the high-level knowledge description. At this purpose, they propose various methodologies based on formal models that reveal hierarchies or tree-based structures, such as Formal Concept Analysis (FCA), Conceptual Ontological Graph (COG); fuzzy modifiers are introduced to capture the vagueness in the written text, that is hidden behind lexical relations and grammar dependencies; then, they exploit these semantic and lexical connections to get the taxonomy and ontology learning.

Most of these approaches extract knowledge from external sources, but some of them build a conceptual structure based exclusively on the analysed text corpora. External support includes both syntactical and semantic sources and tools, for instance, WordNet, whose synsets yield synonyms for each term sense, useful to contextualize concepts. Other external sources are knowledge bases, such as DBpedia, verb-lexicon (e.g. VerbNet [VerbNet]), as well as more sophisticated semantic tools, such as semantic frameworks (e.g. FrameNet [FrameNet]) and ontology-based knowledge organization schema (SKOS [SKOS]). Concept-driven approaches are used as well in Information Retrieval and Natural Language Processing areas.

Some approaches seem to prefer methodologies, capable of producing a topological conceptualisation of data, such as Formal Concept Analysis (FCA), Fuzzy sets, Graph Theory, etc. which are largely used to extract relations, patterns and recognize articulated concepts and topics. Since the Concept Mining approaches aim at generating more complex topological structures, they often combine methodologies and technologies from the three fields introduced in Section A Layered Multi-Granule Knowledge Model, NLP, IR, SW.

In conclusion, the Text Mining approaches presented in the literature combine methodologies from the three fields and subfields (IR is mainly adopted in the information-driven ones). Topological semantic similarities are the most used similarity measures, since they are more effective than frequency-based and statistical measures to extract relations between terms or concepts. Although, data-driven approaches are based on term frequency-based measures, such as co-occurrence measure, tf-idf, mutual information, to assign a weight to each word, information and concept-driven approaches employ semantic similarity, especially topological measures, in order to better represent complex relationships among articulated concepts. The most used measure act on lexical similarity, to extract hyponymy, hypernymy and WordNet synsets, as well as fuzzy measures, which provide a more sensible evaluation of the ambiguousness about NE and concepts.

The use of external sources seems more useful when dealing with high-level input data, i.e., concepts, or when the modelling requires higher-level conceptualisations. The semantic annotation support is instead frequent in the concept-driven and information-driven approaches, while it is almost missing with data-driven approaches (see [Table 1](#)). The data-driven approaches

indeed, work mainly on row data that generate not very complex knowledge (often composed of term ensembles), so the semantic annotation tools are not required at this stage. The use of external ontology-based tools is instead predominant when the knowledge becomes articulated and generates specialized conceptualizations. Table 3 indeed provides a list of concept-driven approaches whose generated knowledge is enhanced by external semantic sources and databases.

Conclusions

The knowledge extraction and modelling need consolidated Text Mining techniques in order to achieve a clear understanding of semantics inside the text. The natural language interpretation is still an open issue that requires enhanced tasks from different but interrelated research domains, such as Artificial Intelligence, Semantic Web, NLP, etc. This paper presents an open-minded outlook on the main methodologies and new approaches to Concept Mining on text corpora, projected in the data-information-concept continuum. The knowledge has been described through a multi-layer schema that presents for each layer, a different knowledge granularity (from a single word to complex linguistic expressions or concepts) and shows the approaches implementing the corresponding information layer. A classification of the main approaches and works in Text Mining have been presented and discussed, according to these granulation levels, evidencing that generally, approaches modelling the same knowledge level have the same tasks and require the similar structuring of data. It is highlighted how, especially in the big data era, the knowledge structuring is a mandatory task to join ad-hoc methodologies and technologies, to improve the machine-oriented knowledge understanding and to guarantee a global knowledge enrichment.

Biographical Sketch

Danilo Cavaliere received master degree in computer science from University of Salerno, Italy in 2014. From 2015 he is predoctoral fellow at Computer Science Department and then at Department of Information and Electrical Engineering and Applied Mathematics (DIEM). He is currently a PhD student at the University of Salerno, Italy. His research interests are in the areas of artificial and computational intelligence, machine learning, data mining and knowledge discovery, areas in which he has published some paper.

Sabrina Senatore received MS degree in computer science from University of Salerno, Italy in 1999 and the PhD degree in computer science from University of Salerno, in 2004. From 2005 she is a faculty member at the University of Salerno. Her current position is associate professor of Computer Science at Department of Information and Electrical Engineering and Applied Mathematics, of the University of Salerno, Italy. She is a member of IEEE CIS Task Force on Intelligent Agents (TFIA) and she is also an editorial board member of the Applied Intelligence Journal and International Journal of Computational Intelligence Theory and Practice. Her current research interests include the development and application of intelligent systems based on the combination of techniques from Soft Computing, Computational Intelligence, Text Mining, Web Information Retrieval, Semantic Web, Machine Learning and Software Agents, areas in which she has published numerous papers.

Vincenzo Loia received BS degree in computer science from University of Salerno, Italy in 1985 and the MS and PhD degrees in computer science from University of Paris VI, France, in 1987 and 1989, respectively. From 1989 he is Faculty member at the University of Salerno. His current position is as Chair and Professor of Computer Science at Department of Management and Innovation Systems. He is the coeditor-in-chief of Soft Computing and the editor-in-chief of Ambient Intelligence and Humanized Computing, both from Springer. He is an associate editor of various journals, including the IEEE Transactions on System, Man and Cybernetics: Systems; IEEE Transactions on Fuzzy Systems; IEEE Transactions on Industrial Informatics; IEEE Transactions on the IEEE Transactions on Cognitive and Developmental Systems. His research interests include soft computing, agent technology, Web intelligence, Situational Awareness. He was principal investigator in a number of industrial R/&D projects and in academic research projects. He is author of over 390 original research papers in international journals, book chapters, and in international conference proceedings. He holds several roles in IEEE Society in particular for Computational Intelligence Society (Chair of Emergent Technologies Technical Committee, IEEE CIS European Representative, Vice-Chair of Intelligent Systems Applications Technical Committee).

Text Mining for Bioinformatics Using Biomedical Literature

Nomenclature

DS	Distant supervision
IE	Information extraction
ML	Machine learning
NER	Named entity recognition

NLP	Natural language processing
POS	Part-of-speech
RE	Relationship extraction
UMLS	Unified Medical Language System

Introduction

Biomedical literature is one of the major sources of current biomedical knowledge. It is still the standard method researchers use to share their findings, in the form of articles, patents and other types of written reports (Hearst, 1999). However, it is essential that a research group working on a given topic is aware of the work that has been done on the same topic by other groups. This task requires manual effort and may take a long time to complete, due to the large quantity of published literature. One of the largest sources of biomedical literature is the MEDLINE database, created in 1965 and accessible through PubMed. This database contains over 23 million references to journal articles in the life sciences, and more than 860,000 entries were added in 2016. There are also other document repositories relevant to biomedicine, such as the European Patent Office, and [ClinicalTrials.gov](https://clinicaltrials.gov/).

Automatic methods for Information Extraction (IE) aim at obtaining useful information from large datasets, where manual methods would be unfeasible. Text mining aims at using IE methods to process text documents. The main challenge of text mining is in developing algorithms that can be applied to unstructured text to obtain useful structured information. Biomedical literature is particularly challenging to text mining algorithms for several reasons. The writing style differs from other types of literature since it is more formal and complex. Furthermore, different types of documents have different styles, depending on whether the document is a journal paper, patent or clinical report (Friedman *et al.*, 2002). Finally, there are a wide variety of terms that can be used, referring to genes, species, procedures, and techniques and, within each specific term, it is also common to have multiple spellings, abbreviations and database identifiers. These issues make biomedical text mining an interesting field for which to develop tools, due to the challenges that it presents (Cohen and Hunter, 2004).

The interactions found in the biomedical literature can be used to validate the results of new research or even to formulate new hypotheses to be tested experimentally. One of the first demonstrations of the hidden knowledge contained in a large literature was Swanson's ABC model (Swanson, 1990), who found that dietary fish oils might benefit patients with Raynaud's syndrome, by connecting the information present in two different sets of articles that did not cite each other. This inference has been independently confirmed by others in clinical trials (DiGiacomo *et al.*, 1989). In the same study, Swanson provided two other examples of inferences that could not be drawn from a single article, but only by combining the information of multiple articles. Considering that, since that study, the number of articles available has grown immensely, it is intuitive that many new chemical interactions might be extracted from this source of information.

More recently, bioinformatics databases have adopted text mining tools to more efficiently identify new entries. MirTarBase (Chou *et al.*, 2016) is a database of experimentally validated miRNA-target interactions published in journal papers. The curators of this database use a text mining system to identify new candidate entries for the database, which are then manually validated. This system was necessary due to the important role miRNAs have been found to play in human diseases over the last decade, leading to a high number of papers published about this subject. The introduction of the system as part of the workflow has led to a 7-fold increase in the number of interactions added to the database.

Text mining has generated much interest in the bioinformatics community in recent years. As such, several tools and applications have been developed, based on adaptations of text mining techniques to diverse problems and domains. This article provides a survey of biomedical text mining tools and applications that demonstrate the usefulness of text mining techniques. The rest of the paper consists of the following: Section Background/Fundamentals provides the basic concepts of text mining relevant to this article, Section Text Mining Toolkits describes some toolkits that can be used to develop text mining tools, Section Biomedical Text Mining Tools describes the most used text mining tools, and Section Applications describes applications built using those tools that have been distributed to the general public. Section Community Challenges provides a summary of the community challenges organized to evaluate biomedical text mining tools. Finally, Section Future Directions suggests future directions for biomedical text mining tools and applications, and Section Closing Remarks summarizes the main conclusions of the article.

Background/Fundamentals

When developing and using text mining tools, it is necessary to first define what type of information should be extracted. This decision will then influence the datasets to be considered, which text mining tasks will be explored, and which tools will be used. The objective of

this section is to provide an overview of the options available to someone interested in developing a new text mining tool or using text mining for their work. The concepts presented are simple to understand and applicable to various problems.

NLP Concepts

Natural Language Processing (NLP) has been the focus of many researchers since the 1950s (Bates, 1995). The main difference between NLP and text mining is the objective of the tasks. While NLP techniques aim at making sense of the text, for example, determining its structure or sentiment, the objective of text mining tasks is to obtain concrete structured knowledge from text. However, there is overlap between the two fields, and text mining tools usually make use of NLP concepts and tasks.

The following list defines NLP concepts relevant to text mining.

Token: a sequence of characters with some meaning, such as a word, number or symbol. The NLP task of identifying the tokens of a text is known as tokenization. It is of particular importance to text mining since most algorithms will not consider elements smaller than tokens.

Part-of-speech (POS): the lexical category of each token, for example, noun, adjective, or punctuation. The category imparts additional semantics to the tokens. Part-of-speech tagging is an NLP task that consists in classifying each token automatically.

Lemma and stem: the base form of a word. The lemma represents the canonical form of the word, corresponding to a real word. The stem does not always correspond to a real word, but only to the fragment of a word that never changes. For example, the lemma of the word “induces” is “induce” while the stem is “induc-”.

Sentence splitting: the NLP task consisting of identifying the sentence boundaries of a text. The methods used to accomplish this task should consider the difference between a period at the end of a sentence, and at the end of an acronym or abbreviation. It is desirable to break a document into sentences because they represent unique ideas. Although the context of the whole document is also important, extracting the knowledge of each sentence independently can provide useful results.

Entity: a segment of text with relevance to a specific domain. An entity may be composed of one or more tokens. Entity types relevant to biomedicine include genes, proteins, chemicals, cell lines, species, and biological processes.

Text Mining Tasks

Text mining tools focus on one or more text mining tasks. It is necessary to define these tasks properly so that it is possible to choose the type of tools that should be used for a given problem. Furthermore, these tasks are used to evaluate the performance of a tool on community challenges. The text mining tasks presented here are common to all domains and sources of text, although the performance of the methods on different domains may differ, i.e., a method that has a good performance on patent documents may not perform as well on clinical reports, due to the different characteristics of the text. The common final objective of these tasks, as to all text mining, is to extract useful knowledge from a high volume of documents, while the extracted knowledge can be useful for several applications, which will be described in Section Applications.

Topic modeling: the classification of documents according to their topics or themes. The objective of this task is to organize a set of documents to identify which documents are more relevant to a given topic (Blei, 2012). Related tasks include document triage (Buchanan and Loizides, 2007) and document clustering.

Named Entity Recognition (NER): consists of identifying entities that are mentioned in the text. In most cases, the exact location of each entity in the text is required, given by the offset of its first and last character. In some cases, discontinuous entities may be considered, therefore requiring multiple offset pairs. The classification of entity properties such as its type (e.g., protein, cell line, chemical) can be included in this task (Nadeau and Sekine, 2007).

Normalization: consists of matching each entity to an identifier belonging to a knowledge base that unequivocally represents its concept. For example, a protein may be mentioned by its full name or by an acronym; in this case, the normalization process should assign the same identifier to both occurrences. The identifiers can be provided by an external database or ontology (Tsuruoka *et al.*, 2008). Related tasks include named entity disambiguation (Bunescu and Pasca, 2006), entity linking, and harmonization.

Relationship Extraction (RE): the identification of entities that participate in a relationship described in the text. Most tools consider relations between two entities in the same sentence. Biomedical relations commonly extracted are protein-protein and drug-drug interactions, see (Segura-Bedmar *et al.*, 2014), for example.

Event extraction: can be considered an extension of the relationship extraction task, where the label of the relationship and role of each participant is specified. The events extracted should represent the mechanisms described in the text (Ananiadou *et al.*, 2010). Related task: slot-filling.

Text Mining Approaches

To accomplish the tasks described above, text mining tools employ diverse approaches. They may focus on one specific approach, or combine several approaches according to their respective advantages, the latter being more common. Most approaches can also be adapted for performing multiple tasks.

Classic approaches: approaches based on statistics that can be calculated on a large corpus of documents (Manning *et al.*, 1999). Some of the most popular approaches are term frequency – inverse document frequency for topic modeling, and

Table 1 Corpora relevant to biomedical text mining tasks

MLEE	Pyysalo <i>et al.</i> (2012)	Biological events	PubMed abstracts

co-occurrence for relationship extraction. These approaches preceded the popularization of machine learning algorithms, although most current approaches still have a statistical background.

Rule-based methods: consist of defining a set of rules to extract the desired information. These rules can be a list of terms, regular expressions or sentence constructions. Due to the manual effort necessary to develop these rules, text mining tools based on this approach have limited applicability.

Machine learning (ML) algorithms: are used for automatically learning various tasks. In the specific case of text mining, it is necessary to convert the text to a numeric representation, which is the expected input of these algorithms. Text mining tools using ML contain models trained on a corpus, that can then be applied to other texts. In some cases, it may be possible to train additional models using other corpora. Several types of ML approaches can be considered, for example, supervised learning, in which the labels of each instance of the training data are known and used to train the classifier, and unsupervised learning, in which the algorithm learns to classify the data without a labeled training set.

Distant supervision (DS): a learning process which heuristically assigns labels to the data according to the information provided by a knowledge base. These annotations are prone to error, but using ML algorithms adapted to this method, it can provide effective classification models. Distant supervision is sometimes referred to as weak supervision.

Biomedical Corpora

Biomedical corpora are necessary to develop and evaluate text mining tools. The simplest corpora consist of a set of documents associated with a specific topic (e.g., disease, gene, or pathway). For some tasks, such as simple topic modeling tasks, it is enough to know which documents are relevant. However, most ML algorithms require annotated text to train their models. The type of annotations necessary to evaluate a task should be similar to the type of annotations to be extracted by the tools (NER tasks require text annotated with relevant entities, while relationship extraction requires the relations between the entities described in the text to be annotated). The annotations should be manually curated by domain experts according to established guidelines. Inter-annotator agreement measures, such as the kappa statistic (Carletta, 1996), can be used to assess the reliability of the annotations. However, text mining tools may also be used to help curators by providing automatic annotations as a baseline (Winnenburg *et al.*, 2008).

The size of an annotated corpus is limited by the manual effort necessary to annotate the documents. Simpler tasks, such as topic modeling, can be performed more quickly by human annotators, so it is less expensive to develop an annotated corpus for this task. Relationship extraction requires that the annotators first identify the entities mentioned in the text, and then the relationships described between the entities. For this reason, it is more expensive to develop an annotated corpus for this task. Biomedical text mining community challenges have contributed to the release of several annotated gold standards that can be used to evaluate systems. Section Community Challenges provides a summary of these challenges. Table 1 provides a list of annotated biomedical corpora relevant to various text mining tasks.

Text Mining Toolkits

Although biomedical text mining requires specialized approaches to deal with the characteristics of the biomedical literature, general text mining tools can be used as a starting point for more specialized approaches. These general tools can be adapted to specific domains, either by using models trained with biomedical datasets or by developing pre- and post-processing rules developed for this type of text. Text mining toolkits are a type of software that can perform various NLP and text mining tasks. The objective of these toolkits is to provide general-purpose methods for performing various text mining tasks, which can be adapted to specific problems. There are several toolkits available, that can be used to pre-process the data, compare the performance of various tools and approaches, and select the best combination for a specific problem. This section provides a survey of well-known text mining toolkits that have been used as frameworks of biomedical text mining tools. In addition to the toolkits presented here, tools can be developed from scratch using programming languages and libraries that implement specific algorithms.

One of the most widely used text mining toolkits is Stanford CoreNLP (Manning *et al.*, 2014), which aggregates various tools developed by the Stanford NLP team for processing text data. Biomedical text mining tools may use Stanford CoreNLP to pre-

process the data (e.g., for sentence splitting, tokenization and co-reference resolution) and to generate features for machine learning classifiers (e.g., for POS tagging, lemmatization, and dependency parsing).

NLTK (Bird *et al.*, 2009), another NLP toolkit, was implemented as a Python library. This toolkit provides interfaces to various NLP resources, such as Word-Net, tokenizers, stopwords lists, and datasets from community challenges. It is often used by developers who are getting started in text mining, due to its well-designed API, and to the availability of various online tutorials for this toolkit. More recently, another Python-based toolkit was released, spaCy, which is more focused on computational performance, using state-of-the-art algorithms.

ClearTK (Bethard *et al.*, 2014) is a text mining toolkit based on machine learning and the Apache Unstructured Information Management Architecture (UIMA). This framework provides interfaces to several machine learning libraries and feature extractors.

GATE (Cunningham *et al.*, 2013) is one of the few text mining toolkits which has features specially designed for biomedical text mining. This toolkit provides plugins for bioinformatics resources such as Linked Life Data and other ontologies, and specialized biomedical NLP tools. Furthermore, a graphical user interface is available to visualize and edit the data and system architecture.

Biomedical Text Mining Tools

This section describes text mining tools commonly used in bioinformatics. These tools generally focus on one specific task, presenting novel approaches, and are evaluated on gold standards. We focus on tools described in the literature and freely available to the community. Even though the current trend is to make software available on code repositories such as GitHub and Bitbucket, this has not always been the case, and past works may not be accessible if the source code was not shared with the community. The tools described in this section have been used in community challenges and may require considerable technical skill to apply to specific problems since the results provided by their developers often refer to gold standards and not to real-world use-cases. These tools are usually fine tuned to work with English texts, but automatic translation techniques have been shown to be effective when using texts in other languages (Campos *et al.*, 2017). Table 2 provides a list of biomedical text mining tools that are available to the community.

NER and Normalization

Biomedical text mining tools can be organized in terms of the text mining tasks performed. The biomedical community challenges organized in the last decade have motivated several teams to develop tools for bioinformatics and biomedical text mining. The focus of these challenges has been in recognizing genes, proteins and chemical compounds mentioned in texts, and linking those

terms to databases. This leads to an imbalance in the quantity and variety of tools available for NER and normalization when compared to other tasks.

BANNER (Leaman *et al.*, 2008) uses Conditional Random Fields (Sutton and McCallum, 2006) to perform NER of chemical compounds and genes. AB-NER (Settles, 2005) and LingPipe (Carpenter, 2007) use similar approaches, each one combining different techniques to improve the results on gold standards, by optimizing the system architecture and feature selection. LingPipe also performs other NLP tasks, such as topic modeling and part-of-speech tagging, while all three provide ways to train models on new data. More recently, other systems have combined machine learning algorithms and manual rules to achieve better results in the biomedical domain (Savova *et al.*, 2010; Campos *et al.*, 2015; Lobo *et al.*, 2017).

GNormPlus (Wei *et al.*, 2015) is a modular system for gene NER and normalization, performing mention simplification and abbreviation resolution to match each gene to an identifier, with higher accuracy, even when more than one species is involved. It is part of a set of NER tools developed by NCBI for various entity types, which includes tmChem (Leaman *et al.*, 2015), DNorm (Leaman *et al.*, 2013) and tmVar (Wei *et al.*, 2013a). These tools are often evaluated in text mining community challenges.

The GENIA project is responsible for various contributions to biomedical text mining, including an annotated corpus (Kim *et al.*, 2003) and various tools for text mining tasks. GENIA tagger (Tsuruoka and Tsujii, 2005) performs NER of several types of entities relevant to biomedicine (protein, DNA, RNA, cell line and cell types), as well as POS tagging. GENIA sentence splitter (Sætre *et al.*, 2007) is an ML-based tool for identifying sentence boundaries in biomedical texts, trained on the GENIA corpus. Acromine (Okazaki and Ananiadou, 2006) is another tool developed by the same team, with the purpose of providing definitions for abbreviations found in MEDLINE abstracts.

Since the vocabulary used in clinical records is quite different from other biomedical texts, tools have been developed specifically for this type of documents. These tools are based on the Unified Medical Language System (UMLS), a collection of vocabularies associated with the clinical domain. cTakes (Savova *et al.*, 2010) is a Java-based tool for processing clinical text, originally developed at the Mayo clinic, which performs several biomedical text mining tasks. It is possible to use this tool through a graphical user interface. Due to the large size and complex structure of UMLS, tools have been specifically developed just to find UMLS concepts in documents. Such tools include MetaMap (Aronson and Lang, 2010), and LDPMMap (Ren *et al.*, 2014). SimSem (Stenetorp *et al.*, 2011) is a tool for entity normalization, using string matching techniques and machine learning. This tool can match strings to a variety of bioinformatics knowledge bases, such as ChEBI, Gene Ontology, Entrez Gene, and UMLS. Couto *et al.* (2017) introduced a system, MER (Minimal Entity Recognizer), which can be easily adapted to different types of entities. This system requires only a file with one entity per line, and uses a simple matching algorithm to find those entities in text.

Relationship and Event Extraction

For RE, most tools use ML algorithms to classify which pairs of entities mentioned in the text constitute a relationship. In this task, kernel methods and Support Vector Machines are popular. jsRE (Giuliano *et al.*, 2006) uses a shallow linguistic kernel which takes into account the tokens, POS, and lemmas around each entity of the pair. It has been used for various problems, including drug-drug interaction extraction (Segura-Bedmar *et al.*, 2011).

Distant supervision has become particularly relevant to RE tasks because it is more expensive to develop a corpus annotated with relations. (Mallory *et al.*, 2016) developed an approach to gene RE using DeepDive, a general purpose system for training distantly supervised RE models. They applied this approach to a corpus of full-text documents from three journals, using the BioGRID and Negatome databases as reference. Another DS-based tool, IBRel (Lamurias *et al.*, 2017), uses TransmiR, a database of miRNA-gene associations, to extract the same type of relationships from text.

Biomedical event extraction is a complex task, but some tools have been developed. Turku Event Extraction System (TEES) (Björne *et al.*, 2011) identifies complex events based on trigger words and graph methods. This system has been evaluated on multiple community challenges, on event extraction and RE tasks, such as the BioNLP-ST 2011 event extraction task. In the 2016 edition of BioNLP-ST, (Lever and Jones, 2016) presented VERSE, a system for extracting relationships and events from text, and evaluated it on three different subtasks. This system is based on ML algorithms, and has the advantage of being able to extract relationships between entities in different sentences.

Textpresso (Müller *et al.*, 2004) is a system for biomedical information extraction based on regular expressions and ontologies. This system has been applied to various domains, and a portal to search the results obtained on each domain is provided in the web interface.

Applications

Even though it is important to develop methods for specific tasks, those methods will only be useful to the community if they can be easily used to help address biomedical problems. Since recent text mining tools have obtained good performance on evaluation corpora, efforts have been made deliver these tools to the general public. In this section, we present a survey of text mining applications that are available in the form of web pages and APIs that focus on the user experience. Table 3 provides a summary of these applications.

Some biomedical text mining applications simply provide access to a text mining tool via a web application. The user uploads one or more documents, which are processed by the tool in a server, and the results are delivered to the user. Even though this is an

Table 3 Bioinformatics applications that either use text mining tools or their results, accessible from the web

important effort, it assumes that the user already has chosen the documents to be processed, and it depends on downstream applications to use the results. Whatizit ([Rebholz-Schuhmann et al., 2008](#)) is a text mining application that can be used to identify biomedical entities in text using a web browser or API. This application is based on a rule-based text mining system which annotates the documents submitted by users. The entities correspond to entries in biomedical knowledge bases, such as ChEBI and UniProt. The results are presented as a web page, where each entity type is marked with a different color. A similar application is BeCAS ([Nunes et al., 2013](#)), based on the Neji tool. With this application, it is also possible to access the results through a web browser or the API, which can then be exported to various file formats.

Other text mining applications provide pre-processed results, reducing the time necessary to obtain results. For example, PubTator ([Wei et al., 2013b](#)) contains every PubMed abstract, annotated with the NCBI NER tools, and it is updated as new abstracts are added to PubMed. Users can search for a list of abstracts or by keyword. It is possible to create a collection of abstracts, manually fix annotation errors, and download the results. PubTator provides access to the results through an API, for integration with other applications. For example, the Mark2Cure crowdsourcing project uses this API to provide a baseline of automatic annotations to its users, while the HuGE navigator knowledge base ([Yu et al., 2008](#)) relies on PubTator to improve its weekly update process. Another application based on pre-processed results is SciLite, a platform for displaying text mining annotations, which is integrated with the Europe PMC database ([Venkatesan et al., 2016](#)). This application shows a list of biomedical terms associated with each document, allowing users to endorse and report incorrect annotations to improve the text mining method. Biomedical Entity Search Tool (BEST) ([Lee et al., 2016](#)) uses text mining techniques to retrieve entities relevant to user queries. BEST is updated daily with the abstracts added to PubMed, and 10 types of entities are identified in each document.

The STRING database stores information about protein-protein interaction networks ([Szklarczyk et al., 2017](#)). It contains information obtained through various methods, including text mining. The interactions extracted using text mining methods are obtained from PubMed and a collection of full-text documents. The RE method used is based on co-occurrence of proteins in the same document, and presence of trigger words such as "binding" and "phosphorylation by." A related database, STITCH ([Szklarczyk et al. 2016](#)), uses a similar method to identify chemical-protein interactions based on the biomedical literature.

FACTA + ([Tsuruoka et al., 2011](#)) is a text mining application for identifying biomedical events described in PubMed abstracts. It uses both co-occurrence and machine learning approaches to extract relationships from text. The user can perform a keyword search to obtain associated documents and biomedical entities, such as genes, diseases, and drugs. Furthermore, FACTA + can be used to identify indirect relations between a concept and a type of biomedical entity. For example, it is possible to search for a disease name and obtain genes that are indirectly associated with that disease, through an intermediary disease, ranked by a novelty and reliability score.

PolySearch2 ([Liu et al., 2015](#)) can also identify relationships between biomedical concepts based on co-occurrence at the sentence level. With this application, it is possible to obtain all the entities, of a specific type, associated with the input query. The corpora and databases used by this application are stored locally and updated daily to ensure that the complete information is available to the users.

EVEX ([Hakala et al., 2013](#)) is a database of biomolecular events extracted from abstracts and full-text articles using text mining tools such as BANNER and TEES. This database contains more than 40 million associations between genes and proteins, and its data can be downloaded and accessed through an API, although it is not updated regularly. MEDIE ([Miyao et al., 2006](#)) contains biomolecular events extracted from MEDLINE, each event being composed of a subject, a verb, and an object. Using MEDIE, it is possible to search by subject, verb or object (or a combination of the three) and obtain all matching events extracted from the abstracts.

Community Challenges

Text mining challenges are organized regularly, by the community, with the purpose of evaluating the performance of text mining tools. These text mining challenges are open to the community, meaning that any academic or industry team can participate. Each

challenge usually comprises several tasks (sometimes referred to as tracks), each with a specific motivation, objective and gold standard. Each team may submit results to one or more tasks. Furthermore, the teams may develop their own tools, or adapt existing tools to the proposed task.

The task organizers announce the objectives of their task on the official websites of the challenge and on mailing lists. Since there are various data file formats used in text mining, a sample of the data may be provided to the participants at the same time as the announcement. This is also the case of datasets that require data use agreements. Afterward, the training set is provided to the participants, consisting of documents and annotations. This training set is used to develop or adapt tools and systems to the task. A development set may also be provided, similar in size to the training set, to further improve the systems. During the final phase of the challenge, a testing set is sent to the teams, without the gold standard annotations. The teams have a time period to submit the annotations obtained with their tools, which are then compared to the gold standard by the organizers. Each task has a defined set of measures to perform this evaluation and rank the teams. The results are then published on the challenge website and in a task overview paper.

One of the earliest NLP challenges, TREC, mainly focuses on the news domain, but it has included a bioinformatics task in some of its editions (TREC Genomics and TREC Chemistry). In 2003, this challenge had a task for retrieving documents related to gene functions (Hersh and Bhupatiraju, 2003), while in later years, more complex tasks have also been proposed (Hersh and Voorhees, 2009). Other NLP challenges, such as KDD Cup (Yeh *et al.*, 2002) and CoNLL (Farkas *et al.*, 2010), also include bioinformatics tasks. SemEval is a series of semantic analysis evaluations organized yearly, and in the most recent editions, there has been at least one task relevant to bioinformatics (Segura Bedmar *et al.*, 2013; Elhadad *et al.*, 2015; Bethard *et al.*, 2016).

Due to increasing interest in biomedical NLP and text mining, community challenges specifically for this domain have been organized. BioCreative was first organized in 2004, and it consisted of the identification of gene mentions and Gene Ontology terms in articles, and of gene name normalization (Hirschman *et al.*, 2005). Since then, five more editions of this challenge have been organized, with a wide variety of tasks. BioNLP-ST has organized various biomedical IE tasks, usually focused on a specific biological system such as seed development (Chaix *et al.*, 2016), epigenetics and post-translational modifications (Ohta *et al.*, 2011), and cancer genetics (Pyysalo *et al.*, 2015). Other community challenges relevant to biomedical text mining include JNLPBA (Kim *et al.*, 2004), BioASQ (Krithara *et al.*, 2016), i2b2 (Sun *et al.*, 2013), and ShARe/CLEF eHealth (Kelly *et al.*, 2014). Huang and Lu (2016) provides an overview of the community challenges organized over a period of 12 years.

Future Directions

More recent approaches to RE have explored deep learning techniques (Miwa and Bansal, 2016). Deep learning is an ML approach based on artificial neural networks that has become popular in the last few years due to its performance in fields such as speech recognition, computer vision, and text mining (LeCun *et al.*, 2015). In the case of text mining, deep learning is associated with word embeddings, which consist of vector representations of word frequencies, that are used as inputs to the networks. There are still few biomedical text mining systems using deep learning techniques. However, various resources are available for this purpose, such as software toolkits that implement these algorithms, as well as a set of resources generated from biomedical literature (Pyysalo *et al.*, 2013).

As NER, normalization, and relationship extraction tasks improve in terms of precision and recall, semantic and question answering techniques can be developed to explore the extracted information. Semantic similarity is a metric used to compare concepts, usually based on a text corpus or an ontology (Couto and Pinto, 2013). These measures can both improve text mining tools by estimating the coherency of the entities and relations extracted, and be improved by applications that can generate candidate entries that may be missing from the ontology (Pershina *et al.*, 2015). Furthermore, question-answering systems can use semantic similarity methods to provide answers with more accuracy (Lopez *et al.*, 2005).

Closing Remarks

There has been a considerable effort by the text mining community to develop and release tools and applications for bioinformatics and biomedical literature. The tools presented in this article use various methods to automate useful tasks, and they can be used by researchers who want to adapt it to their own needs. This article also presents various applications based on text mining results, which demonstrate real-world use-cases of text mining tools. The evolution of biomedical text mining methods has led to more efficient parsing of biomedical literature. These advances should affect how databases are created and maintained, and how documents are indexed by search engines. We expect that future bioinformatics search engines, instead of simply retrieving documents relevant to the query, will be able to directly answer user queries and generate new literature-based hypotheses.

Biographical Sketch

Andre Lamurias is a researcher at LaSIGE, currently enrolled in the BioSYS PhD programme at Universidade de Lisboa and holding a master's degree in Bioinformatics and Computational Biology from the same institution. His PhD thesis consists in developing text-mining approaches for disease network discovery and systems biology. More specifically, his research work is mainly focused on understanding how textual data from document repositories such as PubMed can be explored to improve our knowledge about biological systems.

Francisco M. Couto is currently an associate professor with habilitation and vice-president of the Department of Informatics of FCUL, member of coordination board of the master in Bioinformatics and Computational Biology, and a member of LASIGE coordinating the XLDB research group and the Biomedical Informatics research line. He graduated (2000) and has a master (2001) in Informatics and Computer Engineering from the IST. He concluded his doctorate (2006) in Informatics, specialization Bioinformatics, from the Universidade de Lisboa. He was on the faculty at IST from 1998 to 2001 and since 2001 at FCUL. He was an invited researcher at EBI, AFMB-CNRS, BioAlma during his doctoral studies. In 2003, he was one of the first researchers to study semantic similarity based on information content in biomedical ontologies. In 2006, he also developed one of the first systems to use semantic similarity to enhance the performance of text mining solutions. In 2011, he proposed the notion of disjunctive common ancestors. In 2013, he participated in the development one of the first similarity measure to exploit and demonstrate the usefulness of the description logic axioms in a biomedical ontology.

Multilayer Perceptrons

Introduction

Artificial Neural Networks are computational techniques that belong to the field of Machine Learning (Mitchell, 1997; Kelleher et al., 2015; Gabriel, 2016). The aim of Artificial Neural Networks is to realize a very simplified model of the human brain. In this way, Artificial Neural Networks try to learn tasks (to solve problems) mimicking the behavior of brain. The brain is composed by a large set of elements, specialized cells called *neurons*. Each single neuron is a very simple entity, but the power of the brain is given by the fact that neurons are numerous and strongly interconnected between them. The brain learns because neurons are able to communicate between each other. A picture of a biological neuron is shown in Fig. 1.

In analogy with the human brain, Artificial Neural Networks are computational methods that use a large set of elementary computational units, called themselves (artificial) *neurons*. And Artificial Neural Networks due their power to the numerous interconnections between neurons. Each neuron is able to only perform very simple tasks, and Artificial Neural Networks are able to perform complex calculations because they are typically composed by many artificial neurons, strongly interconnected between each other and communicating with each other. Before studying complex Artificial Neural Networks, that are able to solve large scale real-life problems, we must understand how the *single neurons* and *simple networks* work. For this reason, we begin the study of Artificial Neural Networks (from now on simply Neural Networks) with a very simple kind of network called *Perceptron*.

Perceptron

Perceptron (Rosenblatt, 1958; Demuth et al., 2014; Rashid, 2016) is a simple Neural Network, that can be composed by one single neuron, or several neurons arranged in a *single layer*. In the continuation of this document, we will study the important concept of “layers” in Neural Network and we will be able to understand why Neural Networks that are composed by more than one layer may be more powerful than Neural Networks composed by a single layer, like the Perceptron. Another limitation of the Perceptron, compared to some other kinds of networks, is that in the Perceptron the flow of the information is uni-directional (from input to outputs). For these reason, the Perceptron is also called a *Feed-Forward Neural Network*.

The Perceptron is composed by one or more output neurons, each of which is connected to several input units by means of connections that are characterized by weights. In analogy with Biology, these connections are called *synapsis*.

Single Layer Perceptron

Let us begin with the simplest possible Perceptron Neural Net: the one composed by just one neuron. The structure of a Single Neuron Perceptron can be represented as in Fig. 2.

Fig. 1 Illustration of a biological neuron and its synapsis.

Fig. 2 Single Neuron Perceptron.

The output is calculated as follows:

$$y = f\left(\sum_{i=1}^n w_i x_i + \theta\right)$$

The function f is called *activation function*. One of the most commonly used activation functions is the so called *threshold* (or “step”) function:

$$f(s) = \begin{cases} 1 & \text{se } s > 0 \\ -1 & \text{altrimenti} \end{cases}$$

This activation function is particularly useful when we want to solve classification problems. For instance, the Perceptron composed by one neuron, with this activation function, can be used to classify a set of vectors $\bar{x}$ in one among two possible classes C_1 and C_2 (binary classification). In such a situation, the single neuron Perceptron classifies the vector $\bar{x}$ into the class C_1 if its output is equal to 1 and into the class C_2 if its output is equal to -1 .

As an alternative to the threshold activation function, there are other possible activation functions that are commonly used:

- Logistic o sigmoidal: $f(x) = \frac{1}{1+e^{-ax}}$ 
sigmoid
- Hyperbolic tangent: $f(x) = \frac{e^x - e^{-x}}{e^x + e^{-x}}$ 
- Gaussian: $f(x) = e^{-x^2}$ 
gaussian

Neural Networks are characterized by a learning (or training) phase, in which the network “learns” to solve the given problem modifying, if needed, the weights of its connections. Once the learning phase is complete, the Neural Network is ready to be used on new data (generalization phase). During the training phase, the single neuron Perceptron receives in input k vectors of data $\{\bar{x}_1, \bar{x}_2, \dots, \bar{x}_k\}$ and the class (C_1 or C_2) to which they belong (i.e., the class in which they must be classified). These data form the training set. During the learning, the Perceptron modifies the weights of its synopsis (with an algorithm, called *learning rule*) in such a way to be able to classify, if possible, all the vectors $\bar{x}_1, \bar{x}_2, \dots, \bar{x}_k$ into the correct class (C_1 or C_2). This is supervised learning, given that the target is known for the data of the training set, and Perceptron is a supervised Neural Network.

The algorithm used by Perceptron to modify the weights (in other words, to learn) is the following.

Perceptron learning rule

1. Initialize the connections with a set of weights generated at random.
2. Select an input vector $\bar{x}$ from the training set. Let y be the output value returned by Perceptron for this input value and d the correct answer (target), that is associated to $\bar{x}$ in the dataset.
3. If $y \neq d$ (i.e. the output calculated by the Perceptron is wrong), then modify the weights of all the connections w_i as follows:

$$\text{if } y > d \quad w_i := w_i - \eta x_i$$

$$\text{if } y < d \quad w_i := w_i + \eta x_i$$

Fig. 3 A straight line separating points belonging to two classes.

4. Go to point 2.

The algorithm terminates when all the vectors in the training set are classified in a correct way or after a given prefixed number of iterations.

Remarks:

- Also the weight of the threshold θ must be modified together with all the other weights of the other connections. Thus, θ from now on will be treated like any other connection (in some cases we will call w_0 its weight) with the particularity that the input of this connection is always equal to 1.
- The parameter η is called *learning rate* and can be a constant or it can change at each iteration. In any case, it has always a positive value.

Let us consider the most possible simple case: the case in which the single neuron Perceptron has only two input units. In this case, once the learning phase is terminated, the values of the weights w_1 and w_2 and of the threshold θ will have been determined. In this situation, it is possible to identify a straight line (it would be a hyperplane in the general case, i.e., when the number of inputs is larger than two):

$$\text{or:} \quad w_1x_1 + w_2x_2 + \theta = 0$$

$$x_2 = -\frac{w_1}{w_2}x_1 - \frac{\theta}{w_2}$$

This straight line allows us to graphically *separate* the two classes C_1 and C_2 .

This straight line has the following properties:

- All the points that belong to class C_1 are “above” the straight line and all the ones that belong to C_2 are “below” (or viceversa).
- The weights vector $\bar{w} = [w_1, w_2]$ is perpendicular to the straight line.
- θ allows us to calculate the distance of the straight line to the origin.

These concepts are shown graphically in [Fig. 3](#) and will be clarified by the following example.

Example of Application of the Perceptron Learning Rule

This example should help us clarify the functioning of the algorithm and many of the concepts discussed so far. Let us consider the following “toy” training set:

(x_1, x_2)	d
$(-2, 6)$	1
$(6, 2)$	1
$(-4, 1)$	-1
$(-10, 4)$	-1

In such a situation, the Perceptron must classify $(-2, 6)$ e $(6, 2)$ into a class and $(-4, 1)$ and $(-10, 4)$ into the other. The first step is the weights initialization. It is done in a random way. Let us assume, as an example, that the generator of random numbers of our programming language has generated the following values for the initial weights:

$$w_1 = 1, w_2 = 2, w_0 = -12$$

Furthermore, let us suppose that we keep the learning rate constant for all the execution of the learning rule and let us consider a threshold (“step”) activation function. Let us draw the points of the training set (using two different symbols for the points that

Fig. 4 The points of the example, and the straight line obtained using the initial weights.

must be classified into the two different classes) and the straight line:

$$x_1 + 2x_2 - 12 = 0$$

This graphical representation is shown in **Fig. 4**. From this graphical representation, it is clear that the straight line *does not* separate the points $(-2, 6)$ and $(6, 2)$ from $(-4, 1)$ and $(-10, 4)$, thus it is necessary to modify the weights (and in this way, also the straight line will be modified).

Let us begin the execution of the Perceptron learning rule in order to modify the weights. Let us consider, for instance, the first point in the training set: $(-2, 6)$ and let us calculate the output of the Perceptron for this point:

$$y = f(-2 + 12 - 12) = f(-2) = -1$$

The classification that the Perceptron does of this point is *not* correct: the result is different from the target value that appears in the training set in correspondence with the observation we are considering. Thus, it is necessary to modify the weights. The Perceptron learning rule does those modifications like this:

$$w_0 = w_0 + \eta x_0 = -12 + (1 \cdot 1) = -11$$

$$w_1 = w_1 + \eta x_1 = 1 + 1 \cdot (-2) = -1$$

$$w_2 = w_2 + \eta x_2 = 2 + (1 \cdot 6) = 8$$

Now let us consider, *for instance*, the second point in the training set and let us calculate the output of the Perceptron *with the new weights*. The point is $(6, 2)$ and the output calculated by the Perceptron is:

$$y = f(-6 + 16 - 11) = f(-1) = -1$$

Also in this case the classification is *not* correct (the output calculated by the Perceptron is different from the target that is the training set associated with the point $(6, 2)$). Given that the classification is not correct, it is necessary to once again modify the weights:

$$w_0 = w_0 + \eta x_0 = -11 + (1 \cdot 1) = -10$$

$$w_1 = w_1 + \eta x_1 = -1 + 1 \cdot 6 = 5$$

$$w_2 = w_2 + \eta x_2 = 8 + (1 \cdot 2) = 10$$

Let us now consider, *for instance*, the third point in the training set: $(-4, 1)$. The output calculated by the Perceptron is:

$$y = f(-20 + 10 - 10) = f(-20) = -1$$

the classification in this case is correct (the output calculated by the Perceptron is equal to the correct value that is in the training set associated with the point $(-4, 1)$). So, the weights do not have to be modified.

Now let us consider the fourth point in the training set: $(-10, 4)$. The output calculated by the Perceptron for this point is:

$$y = f(-50 + 40 - 10) = f(0) = -1$$

Also in this case the classification is correct, so the weights do not have to be modified. At this point, we must iterate once again considering all the points in the training set since the last modification of the weights, because the termination condition of the learning algorithm says that the algorithm terminates only when the Perceptron correctly classifies all the training instances.

Let us consider, *for instance*, the first point in the training set: $(-2, 6)$. We have:

$$y = f(-10 + 60 - 10) = f(40) = 1$$

The classification is correct, thus we do not modify the weights. Now let us consider the second point in the training set: $(6, 2)$. We have:

$$y = f(30 + 20 - 10) = f(40) = 1$$

Fig. 5 The points of the example, and the straight line obtained using the weights obtained at termination of the execution of the Perceptron learning rule.

Also in this case the classification is correct, and so we do not modify the weights. The third and the fourth vector of the training set have already been tested with these weights and they have returned a correct classification. So now the algorithm terminates.

Let us now draw the points of the training set and the straight line with the new weights vector:

$$5x_1 + 10x_2 - 10 = 0$$

This graphical representation is shown in Fig. 5. It is clear that now the straight line correctly separates the points! Furthermore, it is possible to observe that the weights vector $(w_1, w_2) = (5, 10)$ is perpendicular to the straight line. In fact, the straight line can be expressed as follows:

$$x_2 = -\frac{1}{2}x_1 + 1$$

and thus its slope is: $m_1 = -\frac{1}{2}$. While the straight line that extends the weights vector is a straight line that passes through the origin and the point $(5, 10)$, so we can write this straight line as:

$$\begin{aligned} \frac{x_1 - 5}{-5} &= \frac{x_2 - 10}{-10} \\ -\frac{x_1}{5} + 1 &= -\frac{x_2}{10} + 1 \\ x_2 &= 2x_1 \end{aligned}$$

Its slope is: $m_2 = 2$. The condition for two straight lines with slopes m_1 and m_2 to be perpendicular is that: $m_2 = -\frac{1}{m_1}$. So, in our case the two straight lines are perpendicular. Finally, let us calculate the distance to the origin of the straight line:

$$5x_1 + 10x_2 - 10 = 0$$

The formula of the distance of a point (x_1, y_1) to a straight line:

$$w_1x + w_2y + w_0 = 0$$

is given by:

$$d = \frac{|w_1x_1 + w_2y_1 + w_0|}{\sqrt{w_1^2 + w_2^2}}$$

In the case in which (x_1, y_1) is the origin, the previous formula becomes:

$$d = \frac{|w_0|}{\sqrt{w_1^2 + w_2^2}}$$

or:

$$d = \frac{|\theta|}{\|\bar{w}\|}$$

The straight line:

$$w_1x_1 + w_2x_2 + w_0 = 0$$

can always be written in such a way that:

$$\|\bar{w}\| = \sqrt{w_1^2 + w_2^2} = 1$$

To obtain this, it is enough to divide the parameters of the straight line by a given constant k . For instance in the case of the previous straight line:

$$5x_1 + 10x_2 - 10 = 0$$

it can be transformed into:

$$x_1 + 2x_2 - 2 = 0$$

to calculate the constant k all we have to do is:

$$\sqrt{\frac{1}{k^2} + \frac{4}{k^2}} = 1 \Rightarrow \frac{\sqrt{5}}{k} = 1 \Rightarrow k = \sqrt{5}$$

So, if we write the straight line in the following form:

$$\frac{1}{\sqrt{5}} x_1 + \frac{2}{\sqrt{5}} x_2 - \frac{2}{\sqrt{5}} = 0$$

we have:

$$\|\bar{\mathbf{w}}\| = 1$$

This means that $\|\bar{\mathbf{w}}\|$ can always be considered equal to 1 *without loss of generality*.

Perceptron convergence theorem

If a weight vector $\bar{\mathbf{w}}^*$ that allows to obtain $y = d$ for all training instances exists, then the Perceptron converges to a solution (that can be equal to $\bar{\mathbf{w}}^*$ or not) in a finite number of steps *independently from the initial choice of the weights*.

If such a weight vector exists, then the classes are *linearly separable*.

Multiple Class Classification

So far, we have considered problems in which data have to be partitioned into *two* classes (*binary classification*). But what happens if data have to be partitioned in *more* than two classes? (*multiclass classification*). Given a problem in which data must be classified into more than two classes, more than two neurons have to be combined into a network. The Perceptron, by its very definition, can have only one layer of neurons, so, for instance, a Perceptron with m neurons will have a structure like the one shown in Fig. 6.

This Perceptron can separate data into 2^m distinct classes, depending on its binary output. In other words, $y_1, y_2, \dots, y_m$ can be interpreted as a binary number, which "encodes" one of the labels of the classes in which data have to be partitioned. During the learning phase, each single neuron is trained independently with the Perceptron Learning Rule that we have seen so far. So, at the end of this phase, we find a weight vector for each neuron. Using this vector, it is possible (in general) to define a *hyperplane*. In case the network has two inputs, the weights of each neuron identify a straight line. These straight lines can be represented on a Cartesian plane and, at the end of the learning phase, if this phase was successful, they separate the points that belong to the different classes, as in the example shown in Fig. 7. Given that all the separating functions are linear, also in the case of (single layer) Perceptron with more than one neuron, the Perceptron is able to correctly solve a classification problem into m different classes $C_1, C_2, \dots, C_m$ if and only if these classes are *linearly separable*.

Non Linearly Separable Problems. An Example

One of the most well-known and commonly diffused non linearly separable problem is the XOR problem. The XOR function is a boolean function that has two input arguments:

$$y = x_1 \text{ XOR } x_2$$

Fig. 6 Single-layer Perceptron with m output neurons.

Fig. 7 Graphical representation of two straight lines able to separate points from four different classes.

Fig. 8 Graphical representation of the XOR problem.

and whose value is expressed by the following truth table:

x_1	x_2	y
-1	-1	-1
-1	1	1
1	-1	1
1	1	-1

On a Cartesian plane, the XOR function can be represented as in [Fig. 8](#). Clearly, no set of straight lines can exist that can be able to separate the two classes.

Let us proof (by absurd) that the Perceptron is not able to correctly classify the XOR problem. Given that the problem consists into a classification of data which are vectors of cardinality equal to two into two classes, we can consider the case of the Perceptron with two inputs and one single neuron. Let us assume by absurd that this Perceptron is able to correctly classify the XOR problem. Then, we admit that a vector of weights $[w_0, w_1, w_2]$ exists such that the following system of disequations holds:

$$-w_1 - w_2 + w_0 \leq 0 \quad (1)$$

$$w_1 - w_2 + w_0 > 0 \quad (2)$$

$$-w_1 + w_2 + w_0 > 0 \quad (3)$$

$$w_1 + w_2 + w_0 \leq 0 \quad (4)$$

Adding (2) to (3) in the previous system, we obtain:

$$2w_0 > 0 \quad \text{i.e.} \quad w_0 > 0 \quad (5)$$

Replacing (5) in (1), we obtain: $-w_1 - w_2 \leq -w_0$ i.e. $-w_1 - w_2$ is smaller or equal to a quantity that is *strictly negative*, and for this reason it is also strictly negative:

$$-w_1 - w_2 < 0 \quad (6)$$

Now, we replace (5) in (4) and we obtain:

$$w_1 + w_2 \leq -w_0$$

Fig. 9 A two layers Neural Network able to correctly classify all the instances of the XOR problem.

Fig. 10 Feed-forward, multi-layer Neural Network.

In other words, we have obtained that $w_1 + w_2$ is minor or equal to a strictly negative quantity, thus:

$$w_1 + w_2 < 0 \quad \rightarrow \quad -w_1 - w_2 > 0 \quad (7)$$

Inequalities (6) and (7) create a contradiction that allows us to terminate the proof.

We observe that a Neural Network composed by *two layers* of neurons (one neuron for each layer) solves the XOR problem. This network is represented in [Fig. 9](#).

In order to prove that the network shown in [Fig. 9](#) solves the XOR problem, let g the output of the left-most neuron, i.e.:

$$g = f(x_1 + x_2 - 0.5)$$

where f is the threshold (or step) activation function. Then, the output of all the network (that corresponds to the output of the right-most neuron) is:

$$y = f(x_1 + x_2 - 2g - 0.5)$$

For the different input data, we have:

$$\begin{aligned} (x_1, x_2) = (-1, -1) &\rightarrow g = f(-2.5) = -1 \rightarrow y = f(-0.5) = -1 \\ (x_1, x_2) = (-1, 1) &\rightarrow g = f(-0.5) = -1 \rightarrow y = f(1.5) = 1 \\ (x_1, x_2) = (1, -1) &\rightarrow g = f(-0.5) = -1 \rightarrow y = f(1.5) = 1 \\ (x_1, x_2) = (1, 1) &\rightarrow g = f(1.5) = 1 \rightarrow y = f(-0.5) = -1 \end{aligned}$$

Non Linearly Separable Problems and Multi-Layer Neural Networks

In general, non linearly separable problems can be solved using *multi-layer* Neural Networks, i.e., Neural Networks in which *one or more neurons are not directly linked to the output of the network* (we call these neurons hidden neurons, and given that they are generally organized into layers, we call these layers hidden layers) ([Demuth et al., 2014](#); [Rashid, 2016](#); [Minsky and Papert, 1988](#)).

A possible structure of a multi-layer Neural Network is shown in [Fig. 10](#).

This network is called Feed-Forward Neural Network and its main characteristics are:

- The neurons in a given layer receive as input the outputs of the neurons of the previous level.

- There are no inter-level connections.
- All the possible intra-level connections exist between two any subsequent layers.

Typically, these Neural Networks are trained using the Backpropagation learning rule, that is the subject of the next article.

Introduction

As previously discussed, single-layer Artificial Neural Networks are not appropriate to solve non-linearly separable problems. Solid theoretical results tell us that this kind of problem can more suitably be solved using *multi-layer* Artificial Neural Networks (Minsky and Papert, 1988), i.e. Artificial Neural Networks (or simply Neural Networks from now on) in which one or more neurons are not directly linked to the output of the network. In other words, these neurons have the property that their outputs, instead of being part of the output of the network, are used as inputs for other neurons. We call these neurons *hidden neurons*, and given that this kind of networks are generally organized into layers, we call the layers that contain hidden neurons *hidden layers*, in contraposition with the *output layer* that is formed by neurons (that we call *output neurons*) whose outputs form the output of the network. A possible structure of a multi-layer Neural Network is shown in Fig. 1.

A network with such a structure is called *Feed-Forward Neural Network* and its main characteristics are:

- The neurons in a given layer receive as input the outputs of the neurons of the previous layer.
- There are no inter-layer connections.
- All the possible intra-layer connections exist between units of any two subsequent layers.

The motivation for the name we give to these networks (Feed-Forward Neural Networks) resides in the direction of the flux of information circulating in the network while the network itself is working: we can imagine that, in the graphical representation of Fig. 1, the information always goes from left to right. In other words, inputs $x_1, x_2, \dots, x_n$ are propagated *forward* into the network in order to produce the outputs $y_1, y_2, \dots, y_m$. This implies that Feed-Forward Neural Networks, by their very definition, do *not* contain cycles, or, which is equivalent, do not contain any connection from a neuron to the neuron itself, or from a neuron to any neuron of a previous layer (Neural Networks with cyclic connections exist. They are called Cyclic Neural Networks and they have several interesting typical practical applications, but their discussion is outside the scope of this article.).

Typically, feed-forward multi-layer Neural Networks are trained using the Backpropagation learning rule (Haykin, 1998), which is a generalization of another, older and simpler, learning rule called Delta Rule. The Delta Rule was originally defined for single-layer Neural Networks, or even Neural Networks composed by only one neuron. The Backpropagation can be seen as an extension of the Delta Rule to multi-layer Neural Networks. Under this perspective, in order to understand the functioning of the Backpropagation (which is the main objective of this paper), it is a necessary precondition to deeply understand the functioning of the Delta Rule. For this reason, in the next section we present the Delta Rule, and later in this document, we present the Backpropagation. Then, the paper is concluded by discussing the important issue of overfitting, and presenting ideas to appropriately set the parameters of feed-forward multi-layer Neural Networks in order to counteract overfitting.

Adaptive Linear Element, and Delta Rule

Adaptive Linear Element (ADALINE) is a Neural Network that has an architecture very similar to the one of the Perceptron (Rosenblatt, 1958). The learning algorithm used by ADALINE, called *Delta Rule* (Haykin, 1998), can be seen as a generalization and/or variation of the Perceptron learning rule. The difference between the Delta Rule and the Perceptron learning rule consists in

Fig. 1 Feed-forward, multi-layer Neural Network.

Fig. 2 Architectural structure of ADALINE.

the way the output is managed. The Perceptron uses as output the result of an activation function (for instance the threshold activation function) to learn. The Delta Rule uses the result of the summation of the inputs (weighted using the weights of the connections or synapsis), to which it can, or can not, be applied an activation function:

$$\gamma = \sum_{i=1}^m w_i x_i + \theta \quad \text{or} \quad \gamma = f\left(\sum_{i=1}^m w_i x_i + \theta\right)$$

In the continuation of this document, the activation function will always be used, but, for reasons that will be clearer later, when an activation function is used, it is better to use an activation function that does not necessarily return either 1 or -1; more specifically, it is generally better if it returns continuous values. The main difference between the Perceptron learning rule and the Delta Rule is that the Delta Rule compares this calculated output to the desired output, or target, by using an *error*, which is usually quantified by means of a distance between calculated outputs and targets (any distance metric can be used for this aim). Contrarily to the functioning of the Perceptron learning rule, the Delta Rule uses this error as the basis for learning. Given the importance of the concept of error between outputs and targets, the architecture of ADALINE is often represented as in [Fig. 2](#). The reader is invited to compare this architecture to the one of the Perceptron ([Rosenblatt, 1958](#)), and remark the presence of an error function applied to the output γ of the neuron (error function that is not present in the architecture of the Perceptron).

Let us assume that we want to map a set of input vectors $\{\bar{x}_1, \bar{x}_2, \dots, \bar{x}_n\}$ into a set of known desired output values $\{d_1, d_2, \dots, d_n\}$ (the target values, which are known, given that we are in presence of supervised learning (Unsupervised learning Neural Networks also exist and are much used in practice, but a discussion of these Neural Networks is outside the scope of this article.)). Let $\{\gamma_1, \gamma_2, \dots, \gamma_n\}$ be the values respectively returned by ADALINE for each one of these input vectors. The most common error functions (also called *cost functions* in some references) are:

$$E = \frac{1}{n} \sum_{i=1}^n (d_i - \gamma_i)^2$$

and in this case the error is commonly called *mean square error*; or:

$$E = \sum_{i=1}^n |d_i - \gamma_i|$$

and in this case the error is commonly called *absolute error*. Many other error measures can be used besides these ones, but only these ones will be discussed in this document, since they are by far the most used ones.

The Delta Rule looks for the vector of weights $\bar{w}$ that *minimizes* the error function, using a method called *gradient descent* ([Haykin, 1998](#)). This method will be defined shortly. So far, it is important to notice that the *learning* of the Neural Network becomes an *optimization problem*, where the cost function, to be minimized, is the error function E , and the different possible solutions for this optimization problem are the different possible existing vectors of weights $\bar{w}$. The graphical representation of function E can be seen as a multidimensional surface and the objective is to find the point (i.e. the vector of weights) in which this surface has its minimum value. Under this perspective, the dynamics of the Delta Rule can be seen as a navigation strategy in this surface; a strategy that, typically starting from a random point, is able to move towards the minimum.

Before studying the functioning of the Delta Rule, the reader is invited to become aware of the existence of the following theorem, one of the consequences of which represents one of the most important limitations of the Delta Rule itself (and the motivation for the necessity of extending the Delta Rule to define the Backpropagation).

Theorem

If the problem is *linearly separable*, then the surface of the E function is *unimodal*, i.e. it contains *only one global minimum* and *no other local minima*.

The objective of the Delta Rule is simply modifying the weights in an iterative way, in order to guarantee that the error E decreases at each one of these steps. Thus, it is easy to understand that, if the problem is not linearly separable and thus the surface of the error function is multimodal, it is possible that ADALINE gets trapped into a local minimum, different from the global one.

On the other hand, for linearly separable problems, as for the Perceptron, also ADALINE is in general an appropriate method to find an optimal solution and thus solve the problem in a satisfactory way.

To decrease the error E at each step, the Delta Rule uses the gradient descent method. In other terms, the Delta Rule functions in a stepwise fashion, by at each step modifying the weights by a quantity $\Delta \bar{w}$ which is *proportional to the derivative* of function E (with a negative proportionality constant):

$$\Delta \bar{w} = -\eta \frac{\partial E}{\partial \bar{w}}$$

We say that, in this way, the weights are modified *in the negative direction of the gradient of E* . Of course, when the minimum of the E function is reached, its derivative is equal to zero, and thus weights are no more modified and the algorithm terminates.

Just as a matter of case study, let us focus in this section on the absolute error (we will focus on the mean square error later). The objective is to minimize:

$$E = \sum_{i=1}^n |d_i - y_i|$$

where $[d_1, d_2, \dots, d_n]$ are the known target values, and $[y_1, y_2, \dots, y_n]$ are the outputs calculated by a neuron (each output is calculated, as previously explained, using a different input vector). Minimizing the error means to find the vector of weights $[w_1, w_2, \dots, w_m]$ for which E is minimum. Before studying the details of the functioning of the Delta Rule, let us establish the following terminology.

Terminology

- n = number of observations in the training set (so, there are n different target values and the summation in the definition of E ranges from 1 to n);
- m = number of dimensions of each one of the input vectors $\bar{x}_1, \bar{x}_2, \dots, \bar{x}_n$ contained in the training set;
- x_i^j = the i th input value of the j th observation (i.e., the i th coordinate of the $\bar{x}_j$ input vector). Remark that: i ranges from 1 to m , j ranges from 1 to n and x_i^j is one of the values that are used as input to the neuron;
- w_i = weight of the connection between the i th input unit and the neuron. Remark that here i ranges from 0 to m (where w_0 represents the weight of the threshold connection (Rosenblatt, 1958));
- $v_j = \sum_{i=0}^m w_i x_i^j$ = what is calculated by the neuron before the application of the activation function. Remark that, again, j ranges from 1 to n (the neuron performs one different calculation, leading to one different output, for each different observation in the training set);
- $y_j = f(v_j)$ = output of the neuron for the j th observation (where f is the activation function);
- $e_j = |d_j - y_j|$ = error of the neuron of the j th observation (where d_j is the correct value, or target, for the j th observation, which is known in the dataset). Again, both in this and in the previous point, j ranges from 1 to n .

According to the previous terminology, E can be written as:

$$E = \sum_{j=1}^n e_j$$

If we consider again the formula of the modification of the weights, but considering this time only one coordinate w_i of the weight vector:

$$\Delta w_i = -\eta \frac{\delta E}{\delta w_i} \quad (1)$$

then our objective can be presented as finding an alternative (and mathematically “convenient”) way of expressing the term $\frac{\delta E}{\delta w_i}$.

To obtain this alternative expression, we first decompose the term $\frac{\delta E}{\delta w_i}$ as follows:

$$\frac{\delta E}{\delta w_i} = \frac{\delta E}{\delta e_j} \cdot \frac{\delta e_j}{\delta y_j} \cdot \frac{\delta y_j}{\delta v_j} \cdot \frac{\delta v_j}{\delta w_i} \quad (2)$$

We now consider the expression on the right of Eq. (2) and “transform” each term one-by-one. Before proceeding, the reader is invited to have a look back at the previous terminology to understand the meaning of e_j , y_j and v_j that have been introduced in Eq. (2). Furthermore, the reader is invited to become aware of the following notation, that will be used in the continuation.

Notation

From now on, given any function

$$\phi(x)$$

we will indicate its derivative with respect to variable x as:

$$\phi'(x)dx$$

This notation is synonymous of $\frac{\delta\phi}{\delta x}$.

Furthermore, when the variable with respect to which we are derivating is “clear from the context”, sometimes we will simply use notation ϕ' to express the derivative of ϕ .

Let us first consider the term $\frac{\delta E}{\delta e_j}$ in Eq. (2). We have;

$$\frac{\delta E}{\delta e_j} = \left(\sum_{k=1}^n e_k \right)' de_j = (e_1 + e_2 + \dots + e_j + \dots + e_n)' de_j = 1$$

In fact, e_j is the variable with respect to which we are performing the derivative, and all other terms are constant.

Now, let us develop the term $\frac{\delta e_j}{\delta y_j}$ in Eq. (2).

$$\frac{\delta e_j}{\delta y_j} = (|d_j - y_j|)' dy_j$$

We know that:

$$|d_j - y_j| = \begin{cases} y_j - d_j & \text{if } d_j < y_j \\ d_j - y_j & \text{otherwise} \end{cases}$$

So:

$$(|d_j - y_j|)' dy_j = \begin{cases} 1, & \text{if } d_j < y_j \\ -1, & \text{otherwise} \end{cases}$$

Now, let us develop the term $\frac{\delta y_j}{\delta v_j}$ in Eq. (2). Given that: $y_j = f(v_j)$, we have:

$$\frac{\delta y_j}{\delta v_j} = f'(v_j) dv_j = f'_j$$

The notation f'_j is used for simplicity, omitting the variable with respect to which the derivative is performed.

Finally, let us develop the term $\frac{\delta v_j}{\delta w_i}$ in Eq. (2). We have:

$$\frac{\delta v_j}{\delta w_i} = \left(\sum_{k=0}^m w_k x_k^j \right)' dw_i = (w_1 x_1^j + w_2 x_2^j + \dots + w_i x_i^j + \dots + w_m x_m^j)' dw_i = x_i^j$$

At this point, we are able to join all the developed terms of Eq. (2), and obtain a transformed version of that equation:

$$\frac{\delta E}{\delta w_i} = \frac{\delta E}{\delta e_j} \cdot \frac{\delta e_j}{\delta y_j} \cdot \frac{\delta y_j}{\delta v_j} \cdot \frac{\delta v_j}{\delta w_i} = \begin{cases} f'_j x_i^j, & \text{if } y_j < d_j \\ -f'_j x_i^j, & \text{otherwise} \end{cases}$$

So, also Eq. (1), i.e. the formula to update the weights, can be rewritten as:

$$\Delta w_i = -\eta \frac{\delta E}{\delta w_i} = \begin{cases} \eta f'_j x_i^j, & \text{if } y_j < d_j \\ -\eta f'_j x_i^j, & \text{otherwise} \end{cases} \quad (3)$$

Remark that, in this new equation, we do not have anymore the derivative of the error. Now we have the derivative of the activation function.

Now, let us consider the case in which the activation function is the *sigmoid*. The expression of the sigmoid function is:

$$f(x) = \frac{1}{1 + \exp(-x)}$$

So, the derivative of the sigmoid function is:

$$\begin{aligned} f'(x) &= \frac{\exp(-x)}{(1 + \exp(-x))^2} = \frac{1}{1 + \exp(-x)} \cdot \frac{\exp(-x)}{1 + \exp(-x)} \\ &= \frac{1}{1 + \exp(-x)} \cdot \left(1 - \frac{1}{1 + \exp(-x)} \right) = f(x)(1 - f(x)) \end{aligned}$$

Interestingly, it is possible to remark that the derivative of the sigmoid can be expressed as a function of the sigmoid itself. According to the terminology used so far, the output of the neuron on the j th observation is y_j , so if the activation function f is the sigmoid, we can write:

$$f'_j = y_j(1 - y_j)$$

So, if we use the sigmoid as an activation function, Eq. (3) can be rewritten as:

$$\Delta w_i = \begin{cases} \eta y_j(1 - y_j) x_i^j, & \text{if } y_j < d_j \\ -\eta y_j(1 - y_j) x_i^j, & \text{otherwise} \end{cases}$$

In other words, to update the weight of a connection we just need:

- The input entering in that connection (x_i^j);
- The output of the neuron (y_j).

In other terms, for each observation $j=1,2,\dots,n$ in the training set, given that for all $i=1,2,\dots,m$, x_i^j is known, all we need to perform the update of the weights is to calculate the output of the neuron y_j . Once this value is calculated, all the needed information to perform the update of the weights is known. The reader is also invited to remark that, after some mathematical passages, the gradient descent formulation has been transformed into a much simpler equation, which does not even contain any derivative calculation, in case the used activation function is the sigmoid.

As conclusion, the Delta Rule Algorithm for the sigmoid activation function is:

Delta Rule (in case of sigmoid activation function):

- Initialize all connections with random weights;
- **repeat until** a termination condition is satisfied:
 1. Select a training observation j
 2. Calculate the output of the neuron for this observation:

$$y_j = f\left(\sum_{i=0}^m w_i x_i^j\right)$$

3. **if** y_j approximates d_j is a satisfactory way

then do nothing and go to point 1.

else for each connection $i=1,2,\dots,m$:

if $y_j < d_j$

then $w_i = w_i + \eta y_j (1 - y_j) x_i^j$

else $w_i = w_i - \eta y_j (1 - y_j) x_i^j$

end if

end if

end repeat

Possible termination conditions of this algorithm are:

- the output of the neuron approximates the target value in a satisfactory way for each training instance (observation), or
- prefixed maximum number of iterations (parameter) was performed.

Also, remark that, contrarily to what typically happens for the Perceptron, the output of the activation function in the Delta Rule is a continuous value. So, our objective is that this value approximates the target "in a satisfactory way", more than being exactly identical to the target. In general, the definition of "satisfactory" is defined by means of a prefixed error threshold ε . In this way, for a given training instance j , y_j is considered to approximate "in a satisfactory way" the corresponding target d_j is and only if: $|d_j - y_j| \leq \varepsilon$.

In the continuation, we the objective of clarifying each step of the Delta Rule algorithm, we present a simulation of execution of that algorithm on a simple numeric example.

Example (application of the delta rule)

Let us consider the following "toy" training set:

(x_1, x_2)	d
$(-2, 6)$	1
$(6, 2)$	1
$(-4, 1)$	0
$(-10, 4)$	0

The objective of this example is to simulate, for some steps, the execution of the Delta Rule algorithm using this training set. Intuitively, this training set represents a simple classification problem, whose objective is to find a model able to classify observations $(-2, 6)$ and $(6, 2)$ into one class (labelled as 1) and observations $(-4, 1)$ and $(-10, 4)$ into another class (labelled as 0).

The first step is the weights initialization. It is typically done in a random way. Let us assume, as an example, that the generator of random numbers of our programming language has generated the following values for the initial weights (exactly as in the example that we have studied previously for the Perceptron):

$$w_1 = 1, \quad w_2 = 2, \quad w_0 = -12$$

Furthermore, let us suppose that we keep the learning rate constant for all the execution of the learning algorithm (and let that constant value be $\eta=0.1$) and let us consider a sigmoid activation function.

Let us assume that we select the first observation (first line) in the dataset (i.e. $\bar{x}_1 = (-2, 6)$). Let us calculate the output of the neuron for this observation (all the calculations will be truncated at the second decimal digit from now on):

$$y_1 = f(w_0 + w_1x_1 + w_2x_2) = f(-12.0 + 1.0 \cdot (-2.0) + 2.0 \cdot 6.0) = 0.12$$

The corresponding target d_1 is equal to 1.0, so we have that $y_1 < d_1$, so we update the weights like follows: for each $i=0,1,2$:

$$w_i = w_i + \eta \cdot y_1 \cdot (1 - y_1) \cdot x_i^1$$

So:

$$w_0 = w_0 + \eta \cdot y_1 \cdot (1 - y_1) \cdot 1 = -12.0 + 0.1 \cdot 0.12 \cdot 0.88 = -11.99$$

$$w_1 = w_1 + \eta \cdot y_1 \cdot (1 - y_1) \cdot x_1^1 = 1.0 + 0.1 \cdot 0.12 \cdot 0.88 \cdot (-2.0) = 0.98$$

$$w_2 = w_2 + \eta \cdot y_1 \cdot (1 - y_1) \cdot x_2^1 = 2.0 + 0.1 \cdot 0.12 \cdot 0.88 \cdot 6.0 = 2.06$$

The new weights are:

$$w_0 = -11.99, w_1 = 0.98, w_2 = 2.06$$

And the new output is:

$$y = f(w_0 + w_1x_1 + w_2x_2) = f(-11.99 + 0.98 \cdot (-2.0) + 2.06 \cdot 6.0) = 0.17$$

The new output is closer to the target than the previous one.

Let us now assume that at the next step we select *the same* input observation (which is possible, given that the Delta Rule algorithm does not impose any prefixed strategy, or order, to select the next observation), and let us perform another iteration of the algorithm. We are still in a situation where $y_1 < d_1$, so weights are modified as follows:

$$w_0 = w_0 + \eta \cdot y_1 \cdot (1 - y_1) \cdot 1 = -11.99 + 0.1 \cdot 0.17 \cdot 0.83 = -11.98$$

$$w_1 = w_1 + \eta \cdot y_1 \cdot (1 - y_1) \cdot x_1^1 = 0.98 + 0.1 \cdot 0.17 \cdot 0.83 \cdot (-2.0) = 0.95$$

$$w_2 = w_2 + \eta \cdot y_1 \cdot (1 - y_1) \cdot x_2^1 = 2.06 + 0.1 \cdot 0.17 \cdot 0.83 \cdot 6.0 = 2.15$$

The new weights are:

$$w_0 = -11.98, w_1 = 0.95, w_2 = 2.15$$

And the new output is:

$$y = f(w_0 + w_1x_1 + w_2x_2) = f(-11.98 + 0.95 \cdot (-2.0) + 2.15 \cdot 6.0) = 0.27$$

As we can see, this results is even closer to the target than at the previous iteration.

Discussion

The objective of the previous example is to convince the reader that:

- The Delta Rule is a very nice way of implementing gradient descent, fast and easy to execute and (in case the used activation function is the sigmoid) without having to calculate any derivative;
- Gradient descent actually works, in the sense that, at every step, the output is closer to the target than at the previous one. In other words, the error decreases at every step.

However, as mentioned earlier while we were studying the Perceptron, the problem of the previous example is linearly separable. So, as the previous Theorem tells us, the error surface is unimodal (no local optima), and decreasing the error at each step will bring us arbitrarily close to the target. But if the problem was non-linearly separable, as we already know, the error surface may contain local optima. For this reason, we need to generalize the Delta Rule to multi-layer Neural Networks. This will be done in the next section, presenting the Backpropagation.

Backpropagation

Looking at the structure of the multi-layer network represented in Fig. 1, a question arises natural: why cannot we use any of the learning rules that we have studied so far (like for instance the Perceptron learning rule, or the Delta rule) for all neurons independently? The answer is straightforward: all the learning rules that we have studied so far use the target value of the neurons as an information for learning. For instance, as we have seen in the previous section, the Delta Rule uses target values to calculate an error between outputs and targets, and the objective is to minimize that error. We obviously can do it for the output neurons in the network of Fig. 1, but we clearly cannot do it for the hidden neurons, where we do not have any notion of an existing target value. So, the Backpropagation learning rule works exactly like the Delta Rule on the output neurons, but extends the Delta Rule, so that it can function also for updating the weights entering in the hidden neurons.

The Backpropagation (Haykin, 1998) is the most common learning rule for multi-layer Neural Networks (sometimes also called multi-layer Perceptron or Feed-Forward Neural Networks). The basic idea of the Backpropagation is the following: the errors of the *output neurons* are *propagated backwards* to the *hidden neurons*. In other words: the error of a *hidden neuron* is defined as the sum of all the errors of all the *output neurons* to which it is directly connected.

The Backpropagation can be applied to networks with any number of layers, but the following theorem holds:

Universal Approximation Theorem

Only one layer of hidden neurons is sufficient to approximate any function with a finite number of discontinuities with arbitrary precision, provided that the activation functions of the hidden neurons are *non linear* (Hornik *et al.*, 1989).

This is one of the reasons why one of the most used configurations of a Feed-Forward multi-layer Neural Network is with only one layer of hidden units, and using a sigmoidal activation function which is non-linear:

$$f(x) = \frac{1}{1 + e^{-x}}$$

The reader is also invited to remark that this is the second good reason for using the sigmoid as an activation function. The first one has been seen in the previous section, and it consists in the fact that, in case the sigmoid is used as an activation function, we are able to transform the gradient descent method in a very simple equation, where no derivative needs to be calculated.

Backpropagation is composed by one *forward step* and one *backward step*. In the forward step, the weights of the connections remain unchanged and the outputs of the network are calculated propagating the inputs through all the neurons of the network. At this point, the error of each output neuron is calculated. The backward step consists in the modification of the weights of each connection. This calculation is made in the following way:

- for the output neurons, the modification is done by means of the Delta Rule;
- for the hidden neurons, the modification is done by *propagating backwards* the error of the output neurons: the error of each hidden neuron is considered as being equal to the sum of all the errors of the neurons of the subsequent layer.

The weights of the connections that enter in each neuron are updated using the formula:

$$w_{ij} = w_{ij} + \Delta w_{ij}$$

where w_{ij} is the weight of the connection between unit i and unit j and:

$$\Delta w_{ij} = -\eta \frac{\partial E}{\partial w_{ij}}$$

In order to calculate Δw_{ij} , as for the Delta Rule, we start from gradient descent, distinguishing the cases of update of the weights of the connections entering into the output neurons and the hidden neurons. These two different cases are presented in the next two sections, respectively.

Weights update – Output neurons

For the output neurons, the process is exactly identical to the one that we have seen for the Delta Rule. The reader is invited to repeat the mathematical passages, using this time the mean square error (instead of the absolute error, as it was done in the previous section for the Delta Rule). By doing this, the reader should be able to verify that the weight of each synapsis connecting the i th hidden neuron to the j th output neuron should be updated as:

$$\Delta w_{ij} = \eta (d_j - y_j) f'_j z_i$$

where d_j is the target value for the j th output neuron, y_j is the output of the j th output neuron, f'_j is the derivative of the activation function of the j th output neuron and z_i is the output of the i th hidden neuron.

If the activation function is the sigmoid, this gives:

$$\Delta w_{ij} = \eta (d_j - y_j) y_j (1 - y_j) z_i$$

This is straightforward to calculate, after that the forward pass of the algorithm has been performed, and so the outputs of all the neurons have been calculated.

If we now “isolate” all the terms concerning the j th output neuron and we define:

$$\beta_j = (d_j - y_j) y_j (1 - y_j) \quad (4)$$

We can conclude that

$$\Delta w_{ij} = \eta \beta_j z_i \quad (5)$$

This last equation will be used after that we will have learned how to modify the weights of the connections entering into the hidden neurons. More specifically, we will discover that those weights can be modified by means of an equation that is extremely similar to Eq. (5).

Weights update – Hidden neurons

In order to obtain a way of modifying the weights of the connections entering into the hidden neurons, first of all let us fix some terminology. Let us consider that our network contains just one layer of hidden neurons (the case of any number of hidden layers can be easily obtained from the previous one) and let p_{hi} be the weight of the connection between the h th input unit and the i th hidden neuron (this is the weight that we will have to update for each h and for each i). Also, like in Section Weights update – Output neurons, let z_i be the output of the i th hidden neuron, and let all the rest of the connections and output values follow the same terminology as in Section Weights update – Output neurons. Also, let v_i be the input of the activation function of the i th hidden neuron. In other words:

$$z_i = f(v_i)$$

where f is the activation function, and:

$$v_i = \sum_h p_{hi} IN_h$$

where IN_h is the value of the h th input unit.

As for the case of the output neurons (that use the Delta Rule), also for the hidden neurons, the starting point is given by the gradient descent formulation:

$$\Delta p_{hi} = -\eta \frac{\delta E}{\delta p_{hi}} \quad (6)$$

Also in this case, the previous equation will be transformed into a more “mathematically convenient” formulation. As for the Delta Rule, the first step is decomposing the previous equation into a number of terms. In this case, let us rewrite the term $\frac{\delta E}{\delta p_{hi}}$ as follows:

$$\frac{\delta E}{\delta p_{hi}} = \frac{\delta E}{\delta z_i} \frac{\delta z_i}{\delta v_i} \frac{\delta v_i}{\delta p_{hi}} \quad (7)$$

Let us begin by developing the term $\frac{\delta z_i}{\delta v_i}$ of Eq. (7). We have:

$$\frac{\delta z_i}{\delta v_i} = \frac{\delta f(v_i)}{\delta v_i} = f'(v_i)$$

As in the previous section, let us accept the simplified notation f'_i to indicate the derivative of the activation function of the i th hidden neuron, so:

$$\frac{\delta z_i}{\delta v_i} = f'_i$$

Now, let us develop the term $\frac{\delta v_i}{\delta p_{hi}}$ of Eq. (7). We have:

$$\frac{\delta v_i}{\delta p_{hi}} = [IN_1 p_{i1} + IN_2 p_{i2} + \dots + IN_h p_{ih} + \dots]' dp_{ih} = IN_h$$

In fact, the derivative is performed with respect to variable p_{hi} and all other terms in the summation are constant.

Finally, let us develop the term $\frac{\delta E}{\delta z_i}$ of Eq. (7). In this case, we have to remember that E , i.e., the error of the i th hidden neuron, is unknown. Also, we have to remember the fact that the Backpropagation algorithm uses the hypothesis that, by definition, the error of the hidden neurons is equal to the sum of the errors of all the output neurons. In other terms:

$$E = \sum_{k=1}^m EOUT_k$$

where $EOUT_k$ is the error of the k th output neuron. So:

$$\frac{\delta E}{\delta z_i} = \frac{\delta (\sum_{k=1}^m EOUT_k)}{\delta z_i}$$

and using the notion that the derivative of a sum is equal to the sum of the derivatives, we can write:

$$\frac{\delta E}{\delta z_i} = \sum_{k=1}^m \frac{\delta (EOUT_k)}{\delta z_i} \quad (8)$$

But the term $\sum_{k=1}^m \frac{\delta (EOUT_k)}{\delta z_i}$ can also be rewritten as:

$$\sum_{k=1}^m \frac{\delta (EOUT_k)}{\delta z_i} = \sum_{k=1}^m \frac{\delta (EOUT_k)}{\delta e_k} \frac{\delta e_k}{\delta z_i} \quad (9)$$

where e_k is the difference between the target value for the k th output neuron and its output, i.e.:

$$e_k = d_k - y_k$$

Let us now develop the term $\frac{\delta(EOUT_k)}{\delta e_k}$ of Eq. (9). We have:

$$\frac{\delta(EOUT_k)}{\delta e_k} = \left[\frac{1}{2} e_k^2 \right]' de_k = e_k$$

where, as for the case of the output neurons when the mean square error is considered, $\frac{1}{2}$ was used as a coefficient simply because it is “mathematically convenient”. In other terms, using this coefficient, it is possible to eliminate any multiplicative constant in the result of the derivative, simplifying the final result without any impact on the final algorithm.

Let us now develop the term $\frac{\delta e_k}{\delta z_i}$ of Eq. (9). That term can be rewritten as:

$$\frac{\delta e_k}{\delta z_i} = \frac{\delta e_k}{\delta v_k} \frac{\delta v_k}{\delta z_i} \quad (10)$$

where v_k is the input of the activation function of the k th output neuron (in other words: $y_k = f(v_k)$).

Let us first develop the term $\frac{\delta v_k}{\delta z_i}$ of Eq. (10). We have:

$$\frac{\delta e_k}{\delta v_k} = \frac{\delta(d_k - \gamma_k)}{\delta v_k} = \frac{\delta(d_k - f(v_k))}{\delta v_k} = -f'_{OUT_k}$$

where f'_{OUT_k} is the notation that we use to indicate the derivative of the activation function of the k th output neuron.

Finally, let us develop the term $\frac{\delta v_k}{\delta z_i}$ of Eq. (10). We have:

$$\frac{\delta v_k}{\delta z_i} = \frac{\delta(z_1 w_{1k} + z_2 w_{2k} + \dots + z_i w_{ik} + \dots)}{\delta z_i}$$

If we join the last two terms we have developed, we are now able to find a way of expressing $\frac{\delta E}{\delta z_i}$ by rewriting Eq. (8). We have:

$$\frac{\delta E}{\delta z_i} = \sum_{k=1}^m e_k (-f'_{OUT_k}) w_{ik} = - \sum_{k=1}^m e_k f'_{OUT_k} w_{ik}$$

We point out that, in this last expression, the summation runs over all output neurons and w_{ik} indicates the weight between the i th hidden neuron and the k th output neuron, that has already been updated by the Backpropagation algorithm (see Section Weights update – Output neurons).

Joining all the developments made so far, we are finally able to rewrite Eq. (7) as:

$$\frac{\delta E}{\delta p_{hi}} = \frac{\delta E}{\delta z_i} \frac{\delta z_i}{\delta v_i} \frac{\delta v_i}{\delta p_{hi}} = - \sum_{k=1}^m e_k f'_{OUT_k} w_{ik} f'_i IN_h$$

and so we are now able to rewrite Eq. (6), obtaining the following formula to update the weights of the connections entering into the hidden neurons:

$$\Delta p_{hi} = \eta \sum_{k=1}^m e_k f'_{OUT_k} w_{ik} f'_i IN_h \quad (11)$$

where:

- $e_k = d_k - \gamma_k$ is the difference between the target value and the output of the k th output neuron;
- f'_{OUT_k} is the derivative of the activation function of the k th output neuron;
- w_{ik} is the weight of the connection between the i th hidden neuron and the k th output neuron;
- f'_i is the derivative of the activation function of the i th hidden neuron;
- IN_h is the value of the h th input unit.

The reader should now try to convince herself that all the previous quantities are known and, if the activation functions of all the neurons are the sigmoid function, also easy to calculate.

If we now define:

$$\gamma_i = \sum_{k=1}^m e_k f'_{OUT_k} w_{ik} f'_i \quad (12)$$

Eq. (11) can be rewritten as:

$$\Delta p_{hi} = \eta \gamma_i IN_h \quad (13)$$

The reader should recognize that, unless for the name of some involved quantities, Eq. (13) is identical to Eq. (5) for updating the weights of the connections entering into the output neurons.

Furthermore, it is interesting to remark that, in Eq. (12), the term $e_k f'_{OUT_k}$ corresponds to the definition of the quantity β_k given in Eq. (4) for the output neurons. So, assuming that β_k has already been calculated, because the weights of the connections entering into the output neurons are updated before the ones of the connections entering into the hidden neurons, we can simplify the Eq. (12) by writing:

$$\gamma_i = f'_i \sum_{k=1}^m \beta_k w_{ik} \quad (14)$$

Let us now see how, despite the complexity of the previous mathematical steps, the modification of the weights of the connections entering into the hidden neurons is simple, in case we assume that also the hidden units use the sigmoid activation function. In this case, Eq. (14) can be rewritten as:

$$\gamma_i = z_i (1 - z_i) \sum_{k=1}^m \beta_k w_{ik}$$

while Eq. (13) remains:

$$\Delta p_{hi} = \eta \gamma_i IN_h$$

where:

- z_i is the output of the i th hidden neuron, and it is known because it has been calculated in the forward pass of the algorithm, where the outputs of all the neurons have been calculated;
- $\beta_1, \beta_2, \dots, \beta_m$ have already been calculated when updating the weights of the output neurons.
- $w_{i1}, w_{i2}, \dots, w_{im}$ are the weights of the connections entering into the output neurons, and they have already been updated (see Section Weights update – Output neurons).
- IN_h is the value of the h th input unit, and it is of course known from the training set.

As a conclusion, we can only recognize that the Backpropagation is able to update all the weights in the network in a simple and extremely efficient way. The complete Backpropagation algorithm is presented below.

The backpropagation algorithm

Summarizing all the achievements obtained so far, we have that:

- For the generic j th output neuron:
 1. Let d_j be the expected correct output (target);
 2. Let y_j be the calculated output

Calculate:

$$\beta_j = (d_j - y_j) y_j (1 - y_j)$$

1. Let y_i be the i th input of the j th output neuron (i.e. the output of the i th hidden neuron)

then the modification of the weight is:

$$\Delta w_{ij} = \eta \beta_j y_i$$

- For the generic i th output neuron:
 1. Let z_i be the calculated output;
 2. Let $\beta_1, \beta_2, \dots, \beta_m$ be the previously calculated quantities for all output neurons;
 3. Let $w_{i1}, w_{i2}, \dots, w_{im}$ be the weights of the connections joining the i th hidden neuron to all output neurons (already updated at previous step)

Calculate:

$$\gamma_i = z_i (1 - z_i) \sum_{k=1}^m \beta_k w_{ik}$$

1. Let INP_h be the h th input of the i th hidden neuron (i.e. the value of the h th input unit of the network)

then the modification of the weight is

$$\Delta p_{hi} = \eta \gamma_i INP_h$$

After some renaming, we are finally able to write an algorithm for the Backpropagation learning rule:

Backpropagation (in case of sigmoid activation function):

- Initialize all the weights in the network with random values.
- **repeat until** a given termination condition is satisfied
 1. Select a vector $\bar{x}$ of the training set (let $\bar{d}$ be correct output – or target – that can be found in the dataset, corresponding to vector $\bar{x}$). Calculate the output of the network $\bar{y}$ for input $\bar{x}$.

```

2. if  $\bar{y}$  approximates  $\bar{d}$  in a satisfactory way
   then do nothing and go to point 1.
   else:
     2.1 For each output neuron  $j$ , calculate  $\delta_j = (d_j - y_j) y_j (1 - y_j)$  and modify the weights of the connections that enter into
         neuron  $j$  as follows:  $w_{ij} = w_{ij} + \eta \delta_j y_i$ 
     2.2 For each hidden neuron  $j$ , calculate  $\gamma_j = y_j (1 - y_j) \sum_k \delta_k w_{jk}$  (where the sum is calculated over all output neurons
          $k$ ), and modify the weights of the connections that enter into neuron  $j$  as follows:  $w_{ij} = \eta \gamma_j y_i$ 
         (remark that both in both points 2.1. and 2.2.,  $y_i$  is the value entering in neuron  $j$  from source  $i$ , while  $y_j$  is the output of
         neuron  $j$ ).
   end if
end repeat

```

Possible termination conditions for this algorithm can be:

- The correct outputs $\bar{d}$ are approximated from the outputs $\bar{y}$ of the network in a “satisfactory” way for every vector $\bar{x}$ of the training set, or
- A prefixed number of maximum iterations has been executed.

Now that we have been able to obtain an efficient algorithm for training feed-forward multi-layer neural networks, let us discuss how to set some important parameters of this networks and one of the most well-known issues of these networks: overfitting.

Backpropagation – Parameter setting

In this section, ideas on how to use feed-forward multi-layer Neural Networks in practice are presented. In particular, the setting of some important parameters such as the learning rate, the momentum, the size of the training set, the number of layers and the number of hidden neurons is discussed. In this discussion, the focus is on the important issue of overfitting, and methods to limit overfitting in order to bestow on the network a reasonable generalization ability. Before continuing, however, the reader should be aware that, for obvious reasons of space, this section is only introductory and should be considered as being far from complete. In fact, given the huge amount of research published in the field, the objective of covering all the subject by revising all the important contributions would be absolutely utopic in such a short article. More specifically, only some of the most well-known and, so to say, “historical” results are discussed in this section, and summarized in a very simple and intuitive way. For a very recent publication, containing several recent advances on the subject, the reader is referred, for instance, to [Fengyu Cong \(2017\)](#).

Learning Rate η

The parameter η has an influence on the speed of learning of a Neural Network. In particular:

- If η is too small, the learning of the network can be slow.
- If η is too big, the network can be “unstable” (in other words, “oscillations” can happen around the optimal value of the vector of weights).

[Sorensen \(1994\)](#) proposes to begin the algorithm with a relatively big value such as $\eta = 0.1$, and to gradually decrease the value of η during the execution of the algorithm. In this way, for a large part of the applications, we are able to reduce (or even eliminate) the risk of having numerous oscillations around the optimal value of the weights.

Momentum α

In spite of all the achievements obtained so far, another problem remains: it is still possible to find a *local minimum* on the error surface. In fact, if the problem is not linearly separable, the surface of the error function can be multimodal, i.e. there can be the presence of several local minima. The Backpropagation, as it is the Delta Rule, is nothing but a convenient way of expressing the gradient descent formulation. As such, also the Backpropagation, such as it was for the Delta Rule, allows us to decrease the error at each step, but may get trapped into a local minimum of the error surface. To reduce the risk of getting trapped in a local minimum, the Delta Rule and the Backpropagation can be modified by inserting a parameter, called *momentum* α :

$$\Delta w_{ij} = \eta \delta y_i + \alpha \Delta w_{ij}$$

By its very definition, the momentum α is such that $0 \leq \alpha < 1$. The value of the momentum is typically a *random number*, drawn to escape from local minima with a given probability ([Sorensen, 1994](#)).

Local Minima and Hidden Neurons

Sometimes, another way of reducing the risk of getting stuck in local minima of the error surface consists in augmenting the *number* of hidden neurons. But it has also been experimentally shown that in some cases if this number is too high, the risk of

Fig. 3 Typical error rates on the training set and on the test set as the number of hidden units change.

getting stuck into local minima can increase instead of decreasing (Sorensen, 1994). To find the right number of hidden neurons to solve a problem is often an empirical task, based on experience and on the knowledge that we have of the problem. Often, some preliminary experiments are needed to find the right number. A little help (i.e. an heuristic formula that binds the dimension of the training set, the number of hidden neurons, the total number of connections of the network and the average admissible error) is given later in this document.

Number of Vectors in the Training Set

To obtain a good generalization from Neural Networks, we have to keep into account that:

- If the training set is too big, there can be a risk of *overfitting* (i.e., the network is too specialized for the training data).
- If the training set is too small, there can be a risk of *underfitting* (i.e., the network did not learn enough).
- In the case of a network with only one level of hidden neurons, some studies have been done regarding the suitable training set size to use to solve a problem (Baum and Haussler, 1989). This study reports that:
 - if we call ε the average of the admissible errors between outputs and targets on test data, and the average error of the network on the training set is smaller than $\varepsilon/2$,
 - if we call M the number of hidden neurons and W the total number of connections in the network,

then an appropriate number of training vectors is given by:

$$\text{Training set size} = K = O\left(\frac{W}{\varepsilon} \ln\left(\frac{M}{\varepsilon}\right)\right) \quad (15)$$

Number of Layers and Number of Neurons

In a large part of the practical cases, the surface of the error function contains a finite number of discontinuities and thus *only one* layer of hidden neurons is sufficient to approximate the target function with arbitrary precision, provided that the activation functions of the hidden neurons are non linear (Theorem of Universal Approximation (Hornik et al., 1989)). However, finding the right number of neurons to allocate in the hidden layer is still an open problem. Also for this parameter, we have to take into account that:

- If it is too big, we can have the risk of overfitting.
- If it is too small, we can have the risk of underfitting.

Generally, the error rates on the training set and on the test set change, during the learning phase and with the number of hidden neurons, as idealized in Fig. 3. Our objective is to find the number of hidden units M that is able to minimize the error on the test set. To find this value is not easy, because it depends on the problem, but Eq. (15) can be helpful. Often, only practice can help and it is necessary to perform a set of experiments to look for the suitable value M for the application at hand.

Conclusions

This paper has presented the Backpropagation learning rule, probably nowadays the most popular algorithm for training feed-forward multi-layer Neural Networks. Before studying the details of the Backpropagation, the Delta Rule was presented as a method to take advantage, in a practical and efficient way, of the gradient descent technique. Then, the Backpropagation has been presented, as a generalization of the Delta Rule to multi-layer Neural Networks, where the error of a hidden neuron is defined as the sum of the errors of the neurons in the subsequent layer, to which it is directly connected. In this phase, particular emphasis was

given to the method used to update the weights entering into the hidden neurons, while for the output neurons the method is identical to the Delta Rule. Finally, ideas to appropriately set some important parameters, in order to limit overfitting, have been discussed.

Introduction

With *Deep Learning* (DL) we refer to a wide family of machine learning techniques using deep architectures in order to learn complex (non-linear) functions, which can be used to tackle several difficult tasks in challenging application scenarios (e.g., *Computer Vision*, *Natural Language Processing*, *Speech Recognition*, *Recommender Systems* and other AI applications). In a nutshell, the approaches based on deep learning aim at training Artificial Neural Networks (ANNs) composed by a large number of hidden layers, so that the resulting models are both efficient and effective. The intuition behind Deep Neural Networks (DNNs) is that the hierarchical structure devised by the hidden layers provides subsequent levels of abstractions: each layer of the architecture learns a set of features with an higher level of abstraction compared to the previous one. In this way, it is possible to highlight the relevant discriminative features even from low level data, such as pixels of medical images or biological sequences.

Exploiting multiple levels of abstractions, *Deep Architectures* allow to discover highly accurate models, by capturing interactions between set of features directly from raw and noisy data. The latter represents one of the most important and disruptive aspects introduced by the DL framework: no feature engineering or interaction with domain experts are required to build good discriminative features.

Historically, DNNs do not represent a substantial architectural difference from the original neural network models introduced in the 1960s (Haykin, 1998). However, their exploitation was limited, due to the difficulty of training. Researchers reported positive results with architectures composed of two or three levels, but essentially training deeper networks did not yield significantly stronger results.

The impulse to new research in the field was given in the last decade. Particularly relevant in the scientific community is the paper by Hinton *et al.* (2006), where an unsupervised pre-training initialization step for the intermediate layers was introduced that would boost the performance of these networks. From there, new initialization methods were investigated (Bengio *et al.*, 2007; Erhan *et al.*, 2010) and other algorithms for deep architectures were proposed.

Since 2006 deep networks were successfully applied in several tasks and application domains. For the purpose of this book, relevant applications can be devised in the analysis of genomic sequences (Alipanahi *et al.*, 2015; Rizzo *et al.*, 2015) or mining of medical images (Ning *et al.*, 2005; Ciresan *et al.*, 2013; Ronneberger *et al.*, 2015; Gulshan *et al.*, 2016; Esteva *et al.*, 2017).

This article is aimed at introducing the basic concept that characterize DNNs and their principles. Clearly, due to the wide nature of the topic the content of this survey is limited. The interested reader can refer to some reference articles (Bengio, 2009; Le Cun *et al.*, 2015; Schmidhuber, 2015; Prieto *et al.*, 2016; Sze *et al.*, 2017; Liu *et al.*, 2017) and books (Deng and Yu, 2014; Goodfellow *et al.*, 2016; Patterson and Gibson, 2017).

Background

ANNs are models inspired by the neural structure of the brain. The brain basically learns from experience and stores information as patterns. These patterns can be highly complex and allow us to perform many tasks, such as recognizing individual from the image of their faces from many different angles. This process of storing information as patterns, applying those patterns and making inferences represents the approach behind ANNs.

The Perceptron

A neuron is the basic component of a neural network and encompasses some basic functionalities inspired from biology. Notably, a biological neuron is a cell connected to other neurons and acts as a hub for electrical impulses. Fig. 1 provides a graphical sketch of a neuron. A neuron has a roughly spherical cell body called soma, which processes the incoming signals and converts them into output signals. Input signals are collected from extensions on the cell body called dendrites. These output signals are transmitted to other neurons through another extension called axon, which prolongs from the cell body and terminates into several branches. The branches end up into junctions transmitting signals from one neuron to another, called synapses.

The behavior of a neuron is essentially electro-chemical. An electrical potential difference is maintained between the inside and the outside of the soma, due to different concentrations of sodium (Na) and potassium (K) ions. When a neuron receives inputs from a large number of neurons via its synaptic connections, there is a change in the soma potential. If this change is above a given threshold, it results in an electric current flowing through the axon to other cells. Then the potential drops down below the resting potential and neuron cannot fire again until the resting potential is restored (Fig. 2).

Fig. 2 Artificial neuron.

An artificial neuron (also called perceptron) emulates this behavior. There are essentially two phases, illustrated in Fig. 1. First, input signals $x_1, \dots, x_n$ are collected through the connections and a linear combination of such inputs is computed as $a = \sum_{i=1}^N x_i w_i + b$. The linear combination is the input for the second phase, where an activation function emits an output signal y . The activation function mimics the behavior of the threshold on the potential difference: when the value of a is substantially different from a steady state, a signal $y = f(a)$ can be emitted which is modeled according to an *activation function* f .

The simple structure of a perceptron is natural model for supervised learning within a linearly separable space (Mitchell, 1997): for example, by considering the activation function $f(x) = \text{sign}(x)$, a perceptron characterized by a vector $\mathbf{w} = (w_1, \dots, w_n)^T$ of weights and bias b models the binary classification problems where a given input tuple $\mathbf{x} = (x_1, \dots, x_n)^T$ can be classified as *positive* if $\mathbf{x} \cdot \mathbf{w} > -b$ and *negative* otherwise. That is, the pair $(\mathbf{w}, b)$ represent a hyperplane within the n -dimensional space, and each point above the hyperplane can be classified as positive, whereas points below it are classified as negative. Fig. 3 depicts a perceptron characterized by the parameters $\mathbf{w} = (1, -1)$ and $b = 0.5$.

An artificial neural network is essentially a combination of neurons to perform complex transformations of the input space. Fig. 4 shows a very simple ANN where the input space $\mathbf{x}$ is given as input to M different perceptrons. The graphical representation shows essentially two layers. The first layer is the input layer, where each node represents an input dimension x_i . In the second layer, nodes represent perceptrons and encode the structure of Fig. 2. That is, the j -th node in this layer represents a perceptron characterized by parameters $(\mathbf{w}_j, b_j)$ and outputting the value y_j . Thus, each perceptron is activated by the same input value $\mathbf{x}$, but the activation is characterized by different weight. Overall, the network accept an n -dimensional vector $\mathbf{x} = (x_1, \dots, x_n)^T$ as input, and outputs an M -dimensional vector $\mathbf{y} = (y_1, \dots, y_M)^T$. The characterization of the network is given by the parameters $(\mathbf{W}, \mathbf{b})$, where $\mathbf{W} = (\mathbf{w}_1, \dots, \mathbf{w}_M)^T$ is an $M \times N$ matrix where the j -th row represents vector of weights of the respective perceptron, and $\mathbf{b} = (b_1, \dots, b_M)^T$. Thus, in matrix notation, we have

$$\mathbf{y} = f(\mathbf{W} \cdot \mathbf{x} + \mathbf{b})$$

Fig. 5 Multi layer ANN.

Multi-Layer Networks and Deep Networks

The expressive power of a single-layer neural network is limited: for example, a perceptron is only effective for classification tasks where the input space is linearly separable. However, perceptrons can be combined and, in the same spirit of biological neurons, the output of a perceptron can feed a further perceptron in a connected architecture.

Stacking perceptrons into hierarchical layers represents an effective way of increasing the expressive power of a neural network.

Fig. 5 shows the general structure of a multilayer neural network with several hidden layers. The structure can be formally

characterized as follows. A neural network models a nonlinear function $y = \text{net}(\mathbf{x}; \mathbf{w}, \mathbf{b})$ from an input vector $\mathbf{x} \in \mathbb{R}^N$ to an output vector $\mathbf{y} \in \mathbb{R}^M$, controlled by two vectors $\mathbf{w}$ and $\mathbf{b}$ of adjustable parameters. Within a d -layer network, each layer is characterized by a size s_j , two vectors $\mathbf{z}^{(j)}$ and $\mathbf{a}^{(j)}$, where $s_0 = N$ is the size of the input data (i.e., number of units in the input layer), and $s_d = M$ is the size of the output (i.e., number of units in the output layer). Each node within the network is uniquely identified by a pair (h, k) , where h represents the corresponding layer and k the position of the node within the layer. To keep notation uncluttered, we assume that $S = \sum_{j=1}^m s_j$ and the vectors $\mathbf{z}$ and $\mathbf{a}$ span over $\mathbb{R}^S$ where $a_i \equiv a_v^{(h)}$ for some encoding $i = \langle h, v \rangle$. This induces a partial order $j < i$ which holds when $i = \langle h+1, v \rangle$, $j = \langle h, u \rangle$ and the two neurons are connected.

Within this representation, $\mathbf{w}$ is the vector of all the weights w_{ij} such that $j < i$. Furthermore, b_i represent the bias associated to unit i and f_i is the relative activation function. The network basically defines a chain of compositions of activation functions, the length of such chain being bounded by the number of layers. The recursive relationships for this composition are given by the equations

$$z_i = f_i(a_i) \quad (1)$$

$$a_i = \sum_{j < i} w_{ij} z_j + b_i \quad (2)$$

which are illustrated in Fig. 6. When j represents an input node, the value z_j corresponds to the value x_i of the relative input dimension. By contrast, when j represents to an output node, z_j maps directly into the corresponding output y_i for some given i .

Fig. 7(a) shows an example neural network with a single hidden layer. Starting from the input dimension (x_1, x_2) , the network iteratively computes the values a_3, a_4, a_5 (and the corresponding activations z_4, z_5 and z_6), and subsequently the combination a_7 which enables the activation on the output y . We call this iterative process *forward propagation*, and this type of architecture is an example of *feedforward neural network*, since the connectivity graph does not exhibit any directed loops or cycles. Moreover, since each neuron of a layer is connected with each neuron of the next layer, the network is *fully-connected*. The overall function computed by the network is

$$\begin{aligned} y = \text{net}(\mathbf{x}; \mathbf{w}, \mathbf{b}) = & f_6(w_{6,3}f_3(w_{3,1}x_1 + w_{3,2}x_2 + b_3) \\ & + w_{6,4}f_4(w_{4,1}x_1 + w_{4,2}x_2 + b_4) \\ & + w_{6,5}f_5(w_{5,1}x_1 + w_{5,2}x_2 + b_5) + b_6) \end{aligned}$$

To get an intuition why multi-layer neural networks increase the expressive power of a simple perceptron, recall that the latter can only model situations where the input space is linearly separable. The hidden layer in the network represented by Fig. 7(a) contains three perceptrons, where each of them can separate the input space according to a hyperplane. The output layer combines the separation in a unique decision, by enabling the overall architecture to separate regions in convex polygons, as shown in Fig. 7(b).

Fig. 6 Compositionality of a multi-layer NN.

Fig. 7 Simple ANN architecture. (a) Example NN with one hidden layer. (b) Classification by separating convex polygons. each line in the two-dimensional space represents a perceptron. The intersection of the regions delimited by the lines represents the combination of the outputs of the perceptrons.

Fig. 8 Traditional machine learning versus (deep) neural network learning.

Fig. 9 Simple multi layer ANN architecture. (a) Example NN with two hidden layers. (b) Classification by separating non-convex regions. By assuming that each perceptron in the third level represents a convex region, the addition of a new level allows to combine decisions which involve such regions.

The above example helps in understanding the role of intermediate layers within a network. Intermediate layers represent natural progression from low level to high level structure within the data. Whereas input $\mathbf{x}$ represents a low level representation of the data, the vectors $\mathbf{z}^{(h)}$ represent a higher level of abstraction, and each $z_k^{(h)}$ represents a new feature which is devised at level h , based on the data coming at level $h - 1$. In this respect, Neural network learning is different from the traditional machine learning algorithm, as shown in [Fig. 8](#): the latter, indeed, require a manual feature engineering. By contrast, neural network adopt an approach where features are progressively learned directly from the low-level representation, and the feature learning is embedded within the training algorithm itself.

Deep Neural Networks (as opposed to *shallow networks*) exacerbate this feature learning general structure, by exploiting a large number of intermediate levels in order to learn complex functions and to devise several features. In this respect, a DNN emulates the mammal brain ([Thorpe and Fabre-Thorpe, 2001](#)) by processing a given input with several levels of abstractions. Clearly, multiple levels increase the expressive power accordingly: [Fig. 9\(b\)](#) provides an example of the expressive power of a relatively simple neural network with two hidden layers.

Learning a DNN

To the purpose of this article, neural networks represent machine learning models [Mitchell \(1997\)](#) which can be applied for either supervised or unsupervised learning problems. The scheme discussed in the previous section represents essentially a network which learns a function $net(\mathbf{x}; \mathbf{w})$ (From now on, we shall omit explicitly mentioning the bias terms and we shall assume that $\mathbf{W}$ represents the whole parameter set. In fact, biases can be considered as extra nodes with activation fixed at $+1$.) and hence it can be considered as an instance of a supervised learning problem where, given a training set $\mathcal{D} = \{(\mathbf{x}_1, \mathbf{y}_1), \dots, (\mathbf{x}_n, \mathbf{y}_n)\}$, we aim at finding the weight vector $\mathbf{w}$ which best guarantees that the predicted values $\hat{\mathbf{y}}_i = net(\mathbf{x}_i; \mathbf{w})$ match the expected values $\mathbf{y}_i$ with minimal loss.

There are essentially four components which influence the specification of the model:

- The topology of the network, i.e., the number of layers and the connections among neurons which specify the $\prec$ partial order among nodes;
- The learning algorithm;
- The choice of the activation functions to exploit within the nodes;
- The loss function to minimize.

We shall discuss the topology of the next section and in the following subsections we shall examine the remaining aspects.

Gradient Descent and Backpropagation

Within the traditional machine learning jargon, the learning phase takes place by computing the value of the weights in the network, and it is referred as *training* of the network. Once the weights has been learnt, the output can be easily determined by applying the network on a specific input (*prediction*). The goal of the training phase is to compute the weights that minimize a given criterion, called *loss* and represented as a function $L(\mathbf{w}; \mathcal{D})$ of the weights given the training set. This is notably an unconstrained optimization problem which has been extensively studied and several characterizations and solution have been proposed (Nocedal and Wright, 2006). Typically, the approach is to work on iterative hill-climbing solutions which, starting from an initial solution $\mathbf{w}^{(0)}$, progressively update the weights in a way that at each step t , we can guarantee $\mathbf{w}^{(t)} < \mathbf{w}^{(t-1)}$. The algorithm stops when we reach a local minimum, i.e., when the improvement is negligible.

The standard approach in the DNN setting is a first-order method called *Gradient Descent* (Rumelhart et al., 1986). Basically, this method minimizes the loss $L(\mathbf{w}; \mathcal{D})$ by updating the model parameters in a direction opposite to the gradient $\nabla_{\mathbf{w}} L(\mathbf{w}; \mathcal{D})$. In its simplest form, the update is performed by considering the gradient w.r.t. the whole training set $\mathcal{D}$, and the update is given by $\mathbf{w}^{(t+1)} = \mathbf{w}^{(t)} - \eta \nabla_{\mathbf{w}} L(\mathbf{w}^{(t)}; \mathcal{D})$, where η is the *learning rate*.

The problem with the gradient descent is the relatively slow convergence to a local minimum. Second-order methods can also be applied (Shepherd, 1997), such as conjugate gradients and quasi-Newton methods. However, these approaches have not become popular, especially in the context of DNNs, due to issues such as numerical stability, poor approximation of the underlying hessian matrix, or the high computational costs associated. Some tricks can still be exploited, as investigated in Martens (2010). However, by far the most widely adopted optimization techniques for neural networks are those based on gradient descent plus heuristics.

Later in this section we shall discuss in details how the gradient descent algorithm is realized within a neural network. However, it is important to get into the details of the loss function first.

Loss functions

Recall that the training phase is meant to find a set $\mathbf{w}$ of weights that guarantee an optimal matching of the between the actual values $\mathbf{y}_i$ and the values $\hat{\mathbf{y}}_i$ predicted by the network, given $\mathbf{x}_i$. A loss function is meant to measure this matching, and to quantify how far we are from the theoretical optima. Typically, it can be defined incrementally,

$$L(\mathbf{w}; \mathcal{D}) = \sum_{i=1}^n \ell(\mathbf{y}_i, \hat{\mathbf{y}}_i)$$

by relying on a pointwise specification $\ell(\mathbf{y}_i, \hat{\mathbf{y}}_i)$ of the loss for each data given point. In order to be suitable for the gradient descent algorithm and its variants, L has to be differentiable. Several alternative formulations can be devised, depending on the nature of the problem we are modeling. An extensive review be found in Rosasco et al. (2004). Here we review some major instantiations typically used in DNN realizations.

Numeric prediction. When $\mathbf{y}$ represents a real-valued vector, the simplest losses can be expressed in terms of the difference between the expected and the predicted values, either by means of the *Absolute Error*

$$\ell(\mathbf{y}, \hat{\mathbf{y}}) = \sum_{i=1}^M |y_i - \hat{y}_i|$$

or *Squared Error*

$$\ell(\mathbf{y}, \hat{\mathbf{y}}) = \frac{1}{n} \sum_{i=1}^M (y_i - \hat{y}_i)^2$$

Particular cases can be adapted to model more complex situations. For example, when predicting one-dimensional count data, the *Poisson* loss can be applied:

$$\ell(y, \hat{y}) = (\hat{y} - y \log \hat{y})$$

Classification. When $\mathbf{y}$ represents a nominal value, typically both $\mathbf{y}$ and $\hat{\mathbf{y}}$ can be expressed as binary vectors and the absolute loss, also named 0 – 1 loss, can be applied. However, the predicted value $\hat{\mathbf{y}}$ are also likely to get an probabilistic interpretation: that is the output of a network can be interpreted as the response of a multinomial distribution across all the possible class values. Typically, $\mathbf{y}$ is a binary vector and $\hat{\mathbf{y}} \in (0, 1)^D$ is a numeric vector where each $\hat{y}_i$ represents the probability that the response associated to $\mathbf{x}$ is the i -th class. In such a case, the classification loss can be expressed in terms of *Cross Entropy*,

$$\ell(\mathbf{y}, \hat{\mathbf{y}}) = \sum_{i=1}^D y_i \log \hat{y}_i$$

which represents the log-likelihood of the data under the assumption that the response is, indeed, multinomial. Intuitively, cross entropy provides an estimate of the divergence between two probability distributions, if the cross entropy is large, which means that the difference between two distribution is large, while if the cross entropy is small, which means that two distribution is similar to each other.

A particular case can be devised with a binary classification problem: the true output can be expressed by means of a single binary variable y and the cross entropy loss can be expressed as

$$\mathcal{L}(y, \hat{y}) = (y \log(\hat{y}) + (1 - y) \log(1 - \hat{y}))$$

Gradient descent optimization algorithms

We can now review the gradient descent algorithm and its realization in the context of neural networks, called *Backpropagation*. We discussed on how the gradient descent relies on the computation of the gradient $\nabla_{\mathbf{w}} \mathcal{L}$. It is useful to analyze in detail this gradient on specific nodes:

$$\frac{\partial \mathcal{L}}{\partial w_{u,v}} = \sum_{i=1}^n \frac{\partial L_i}{\partial w_{u,v}} \quad (3)$$

where L_i is a placeholder for $\mathcal{L}(\mathbf{y}_i, \hat{\mathbf{y}}_i)$. Remember that $\hat{\mathbf{y}}_i = \text{net}(\mathbf{x}_i; \mathbf{w})$ is a function of the weights, which depends on the weight $w_{u,v}$ only via the input summation a_u , by virtue of the Eqs. (1) and (2). Thus, by applying the chain rule, we have

$$\frac{\partial L_i}{\partial w_{u,v}} = \frac{\partial L_i}{\partial a_u} \frac{\partial a_u}{\partial w_{u,v}}$$

By looking at Eq. (2) we can see that the second term simply corresponds to z_v . We can hence focus on the first term, which we shall denote as δ_u . We can distinguish two situations here:

- u is an output node. In such a case, the computation simplifies into

$$\delta_u = \frac{\partial L_i}{\partial \hat{y}_i} \cdot \frac{\partial \hat{y}_i}{\partial a_u}$$

For example, in the case of 0–1 loss we have $\delta_u = 2(y_i - \hat{y}_i)z'_u$, where z'_u represents the derivative of f_u applied to a_u .

- u is an internal node. In such a case, we can backpropagate the effects of the gradient from the nodes directly connected to u , by applying again the chain rule:

$$\delta_u = \sum_{k: u < k} \frac{\partial L_i}{\partial a_k} \frac{\partial a_k}{\partial a_u} = \sum_{k: u < k} \delta_k z'_u w_{k,u}$$

As we can see, the computation of the gradient has a recursive specification, which starts from the output nodes and propagates backward to the internal nodes. To summarize, the contribution of each tuple to the update of the weights is given by the gradient $\partial L_i / \partial w_{u,v} = \delta_u z_v$, computed in two steps: first, a forward step is accomplished to compute values a_u , z_u and z'_u for each node in the network; second, these values are propagated backwards by means of the δ_u components.

Equipped with the above backpropagation formulas, Vanilla (or Batch) Gradient Descent method, described before in this section, is an intuitive and easy to train a network. However, it relies on the contributions of all tuples in the computation of the gradient, as shown in Eq. (3). This can be very slow or even unfeasible, if the whole amount of data cannot load in main memory. More practical variants of the algorithm have been proposed in the literature (Ruder, 2016). We briefly review some of them. *Stochastic Gradient Descent (SGD)*. This is probably the simplest variant of the GD algorithm. With this method, the update of the weights does not require the gradient on the full dataset: rather it focuses only on a random subset of reduced size, or even a single random tuple. This trick allows to speed-up the convergence. The adoption of a mini-batch typically introduces high variance in the updates, which can be mitigated by adding a *Momentum* (Qian, 1999), i.e., a smoother update which also takes into account the previous update:

$$\mathbf{v}^{(t+1)} = \gamma \mathbf{v}^{(t)} - \eta \nabla_{\mathbf{w}} L_i(\mathbf{w}^{(t)})$$

$$\mathbf{w}^{(t+1)} = \mathbf{w}^{(t)} + \mathbf{v}^{(t+1)}$$

Adaptive learning rates. Both the vanilla and the stochastic version of the GD assume that the learning rate η is fixed for each weight component $w_{u,v}$. By contrast, Adagrad (Duchi et al., 2011) adapts the learning rate component-wise, by rescaling a fixed value proportionally to the sum of the magnitudes of the past component-wise gradients $\sum_t (\nabla_{w_{u,v}} L_i(\mathbf{w}^{(t)}))^2$. This has the natural effect of decreasing the effective step size as a function of time, and the principle is that the updates should be larger for infrequent parameters, and smaller for frequent ones.

Adadelta, RMSprop and Adam are variations of the original method, where different weighting factors are exploited instead of exploiting the sum of the magnitudes of the past component-wise gradients.

Activation Functions

An activation function f_u relative to a network unit u is used to encapsulate non linearity into the network. Non-linear activation functions enable neural networks to approximate arbitrarily complex functions (Cybenko, 1989). By contrast, without the non-linearity introduced by the activation function, multiple layers of a neural network are equivalent to a single layer neural network.

The most common forms of activation functions are the *sigmoids*, which are monotonically increasing functions that asymptotes to some finite value. The *logistic* function $\sigma(a) = (1 + \exp(-a))^{-1}$ is such an example, representing a continuous approximation of *sign* function. Another typical choice is the *hyperbolic function* $\tanh(a) = (\exp(a) - \exp(-a))(\exp(a) + \exp(-a))^{-1}$, which is preferable to the logistic for two main reasons (Le Cun et al., 1998): the derivatives are usually higher, thus allowing faster convergence, and the output space is broader and exhibits an average around zero.

One of the drawbacks of the above mentioned functions, especially in the context of deep networks, is that the gradient near the asymptotes is 0. During backpropagation through the network with sigmoid activation, the gradients in neurons whose output is near the asymptotes are nearly 0. Thus, the weights in these neurons do not update. Also, because of the backpropagation rule, the weights of neurons connected to such neurons are also slowly updated. This problem is also known as vanishing gradient. To alleviate this problem, alternative formulations were adopted. For example the *Rectified Linear Unit ReLu* ($a) = \max(0, a)$) has become popular in deep learning models because significant improvements of classification rates have been reported for speech recognition and computer vision tasks. This function only allows the activation if a neurons output is positive; and allows the network to compute much faster than a network with sigmoid or hyperbolic tangent activation functions, and allows sparsity on the network because random initialization approximately guarantees that half of the neurons in the entire network will be set to zero. Although it is not differentiable around 0, it allows a smooth approximation $\text{ReLU}(a) = \log(1 + \exp(a))$.

Previously in this article, we devised a network where each neuron can admit a different activation function. Although this is in principle possible, the common practice is that all nodes within a layer are equipped with the same activations and it's not unusual that the whole network is equipped with a unique activation function. The only exception is given by output nodes, which require specific activations. Typically, these nodes are equipped with linear activations for modeling numeric responses, or with the softmax function for modeling nominal response over k alternative unordered classes: $\text{softmax}_j(\mathbf{a}) = \exp(a_j) / (\sum_k \exp(a_k))^{-1}$.

Shallow Versus Deep Learning

Compared to shallow networks, DNNs suffered from two main issues: overfitting and training time. Overfitting is essentially due because DNNs represents extremely complex models with millions of parameters which are hence difficult to tune and optimize. An effective control of this phenomenon has been obtained by means of several tricks. We mention some of them and the interested reader can refer to Bengio (2012) and Goodfellow et al. (2016).

- *Regularization* allows to control overfitting by adding weight penalties within the loss function according to some criteria (Bengio et al., 2013), such as weight decay or sparsity.
- Other forms of regularization include *Dropout* (Hinton et al., 2014), i.e., resetting a random number of weights during training. Dropout also helps in decorrelating nodes within the network.
- *Gradient clipping* (Bengio et al., 2013) is another form of regularization, usually exploited to prevent the *gradient exploding* problem (the opposite of vanishing gradient).
- *Initialization and pretraining* by means of unsupervised techniques was also proved effective in the early stages of deep learning research (Hinton et al., 2006; Bengio et al., 2007; Erhan et al., 2010). Recently, better random initialization methods (Glorot and Bengio, 2010) were proved more effective, especially when combined with the adoption of rectified linear units.
- *Data augmentation*, i.e., artificially enlarging the training data by transforming the $\mathbf{x}_i$ inputs in the training set.

The problem of training a network with millions of parameters is also due to the computational time required by training procedure. The adoption of GPUs however has produced significant speedups and consequently has made the training phase more affordable.

Deep Learning Architectures

DL gathers features several layers of non-linear processing and according stacked into a hierarchical scheme. Despite this common characteristics, the DL architectures can vary according to the learning goals and the type of data to consider.

As seen in the previous section, a typical learning task for DNNs is supervised learning. DNNs for supervised learning allow to discover discriminative patterns for classification purposes and assume that labelled data are always available in direct or indirect forms. DNNs for supervised tasks are also called discriminative deep networks. Convolutional Neural Networks and Recurrent Neural Networks are relevant deep architectures for supervised tasks.

However, DNNs can also be used for unsupervised or generative learning, when no or little information about class labels is available. These architecture are aimed at extracting high-order correlation from data for pattern analysis or summarization purposes. Relevant architectures for these tasks are Autoencoders, (Restricted) Boltzmann Machines and Deep Belief Networks.

Fig. 10 Example CNN architecture.

Convolutional Neural Networks

Convolutional Neural Networks (CNN) (Le Cun *et al.*, 1990; Le Cun and Bengio, 1995) represent a biologically-inspired variant of feed-forward networks, where the connectivity between neurons tend to capture the invariance of patterns to distortion or shift in the input data. CNNs architectures commonly assume to work with bi-dimensional data (typically images) as input of the networks. A basic CNN can be devised as a stacking of layers where each of these layers transforms one volume of activations to another. Three main types of layers are used: *Convolutional Layers*, *Pooling Layers*, and *Fully-Connected Layers*. Fig. 10 shows an example CNN architecture that combines these layers to recognize objects within an image.

A convolutional layer produces an higher-level abstraction of the input data, called a *feature map*. Units in a convolutional Layer are arranged in feature maps, within which each unit is connected to local regions in the feature maps of the previous layer and represent a convolution of the input. Each neuron represents a receptive field, which receives as input a rectangular section (a filter) of the previous layer and produces an output according to the stimuli received from this filter. In practice, the activation of the (j,k) -th neuron in a feature map at layer h is given by the application of a filter of size $c \times d$ to the neurons of layer $h - 1$:

$$a_{j,k}^{(h)} = \sum_{l=1}^c \sum_{m=1}^d w_{m,l} z_{j+l,k+m}^{(h-1)}$$

Notice that weights in a feature map are shared. This allows to learn exactly a same feature, independently from the position of the feature within the input layer. Also, compared to fully connected layers, the number of parameters of convolutional layers is greatly reduced, since it only corresponds to the size of the filter multiplied by the number of feature maps we wish to detect.

Pooling layers merge semantically similar features, in order to progressively reduce the spatial size of the representation and the amount of parameters and computation in the network. A typical pooling unit computes an aggregation (e.g., the maximum or the average) of the values a local region within a feature map of a convolutional layer, as shown in figure.

The intuition within the architecture of a CNN is that convolutional/pooling layers detect high-level features within the input, which are hence used as input for a set of fully connected layers devoted to output the final classification. For example, within an image, convolutional layers can progressively detect edges, contours and borders, and the later can be finally used to recognize the object within the image.

Recurrent Neural Networks

The (D)NN models explored so far have no memory and the output for a given input does not assume a temporal dependency from the previous inputs to the network. However, the basic neural network model is flexible enough to model even such dependencies, which typically occur within sequences or time series.

In their most general form, Recurrent Neural Networks (RNNs) (Lipton *et al.*, 2015; Graves, 2012) are nonlinear dynamical systems mapping input sequences into output sequences. RNNs keep internal memory for allowing temporal dependencies to influence the output. In a nutshell, in these networks some intermediate operations generate values that are stored internally in the network and used as inputs to other operations in conjunction with the processing of a later input. Therefore RNNs receive as input two sources, the present and the recent past, which are combined to determine how they respond to new data. Fig. 11 clarifies these relationships.

Basically, RNNs can be thought as feed-forward neural networks featured by edges that join subsequent time steps, including the concept of time within the model. Like feedforward neural networks, these learning architectures do not exhibit cycles among the standard edges but, on the contrary, those that connect adjacent time steps (named *recurrent edges*) may form cycles, including cycles of length one that are self-connections from a node to itself across time. At time t , nodes with recurrent edges receive input from the current data point $\mathbf{x}^{(t)}$ and also from hidden node values $\mathbf{h}^{(t-1)}$ representing the network's

previous state. The output $\mathbf{y}^{(t)}$ at each time t is computed by exploiting as input the hidden node values $\mathbf{h}^{(t)}$ at time t . Input $\mathbf{x}^{(t-1)}$ at time $t-1$ can influence the output at time t and later by way the recurrent connections. The figure shows that the recursive representation on the left is a placeholder for the unfolded representation on the right, where the following recursive relationships hold:

$$\mathbf{h}^{(t)} = f_1(\mathbf{U}\mathbf{x}^{(t)} + \mathbf{W}\mathbf{h}^{(t-1)})$$

$$\mathbf{y}^{(t)} = f_2(\mathbf{V}\mathbf{h}^{(t)})$$

By considering the unfolded representation, it is immediate to notice that a RNN corresponds to a DNN where the depth is given by the sequence length, where the weights are shared among layers and the hidden layers $\mathbf{h}^{(t)}$ are connected to each other to capture temporal relationships within the data.

Learning of the weights can proceed by means of the standard backpropagation algorithm, which is instantiated to the case of the unfolded architecture shown in Fig. 11 and is called *Backpropagation Through Time* (Werbos, 1990).

An important issue with standard RNNs is the difficulty of learning long-range dependencies between data instances that are far from each other. This is due essentially to the deep nature of a RNN, which suffers of the already mentioned vanishing gradient (Pascanu et al., 2013).

To approach this issue, a different architecture was established and proven extremely successful: Long-Short Term Memory (LSTM, Hochreiter and Schmidhuber, 1997). Specifically, this model is an evolution of a standard RNN where each hidden layer is replaced by a *memory cell*, shown in Fig. 12. A memory cell contains a node with a self-connected recurrent edge, ensuring that the gradient can pass across many time steps without vanishing.

The idea behind LSTMs is to enable long-range dependencies by introducing an intermediate storage step within the memory cell, controlled by special neurons called gates. By assuming that a memory cell is associated with a cell state $C^{(t)}$, the gates can add or remove information to the cell state. Basically, gates are sigmoidal units associated with a pointwise multiplication operator, which optionally let information flow through the layer. In particular, the *input gate* $i^{(t)}$ controls how $\mathbf{x}^{(t)}$ contributes to the cell state, the *forget gate* $f^{(t)}$ controls the amount of information to gather from the previous cell state $C^{(t-1)}$, and the *output gate* $o^{(t)}$ controls the generation of the output $\mathbf{y}^{(t)}$ of the node.

Despite their simplicity, LSTMs work surprisingly well in several tasks and either them or their variants represent the most widely adopted application of RNNs.

Fig. 11 Simple RNN architecture. The recurrent edge on the left represents the unfolding of the connections through the network following the length of the sequence. Modified from <http://www.wildml.com/2015/09/recurrent-neural-networks-tutorial-part-1-introduction-to-rnns/>.

Fig. 12 Memory cell structure.

Autoencoders

The architectures discussed so far represent example models for supervised learning. However, deep architectures for generative learning have been investigated as well. Among them, Energy-Based Models (Ranzato *et al.*, 2006) and Deep Autoencoders (Hinton and Salakhutdinov, 2006; Bengio *et al.*, 2007) gained particular attention in recent years (Bengio, 2009; Ngiam *et al.*, 2011).

An autoencoder (also named autoassociator) is a particular feedforward NN architecture where the target of the network is the data itself, and it is mainly exploited for dimensionality reduction tasks or for learning efficient encoding. Basically, it can be considered as an unsupervised feature extraction method. The network structure of an Autoencoder is similar to a Multi-Layer ANN. The simplest structure (shown in Fig. 13(a)) includes three components: (i) an input layer of raw data to be encoded; (ii) a (stack of) hidden layer(s) featuring by a considerable smaller number of neurons; and (iii) an output layer with the same size (i.e. the same number of neurons) of the input layer. An autoencoder is called deep if the number of its hidden layers is large (Fig. 13(b)).

Specifically, an autoencoder can be conceptually thought as composed by two subnets, namely *encoder* and *decoder*. The former allows to learn a mapping $z = \text{enc}(x)$ between the input layer and the hidden layers (*encoding*), whereas the second learns a mapping $y = \text{dec}(z)$ between the features extracted by the encoder and the output layer (*decoding*). Both mappings are defined in terms of nonlinear activation functions that are governed by a set W of weights,

$$z = f_1(Wx)$$

$$y = f_2(W^T z)$$

Again, gradient descent can be applied to learn W that minimizes the reconstruction loss, for example, $\mathcal{L} = \sum_i \|x_i - y_i\|$ (for real-valued vectors x). Deep autoencoders represent essentially the multi-layered version of this basic model, where multiple intermediate representations can be stacked. Since we aim at minimizing the reconstruction error and it difficult to optimize the weights in nonlinear autoencoders that have multiple hidden layers, a typical strategy in to proceed in a greedy levelwise manner, by progressively learning the weights for each level separately.

An effective variant of this architecture is called (*Stacked*) *Denoising Autoencoder* (Vincent *et al.*, 2008). In a nutshell, the purpose of a denoising autoencoder is to act as a regularizer, by trying to reconstruct the original information from noisy data. To this purpose, noise can be applied stochastically to the input x , to obtain a new input $\tilde{x}$ used to compute z and y . By optimizing the reconstruction loss, the weight matrix W learns to regularize the content and to extract features even from noisy input. In this way, it can be used a pre-training strategy for learning DNNs.

Deep Belief Networks

An alternative approach to autoencoders is to assume that the observed data is the result of a stochastic process which can be interpreted in neural network terms.

A *Boltzmann Machine* (Fischer and Igel, 2012) is a parameterized generative model representing a probability distribution, modeled indeed as a neural network with two basic layers. Input units represent a first layer and corresponds to the components of the observations x . Hidden units are meant to model dependencies between the components of the observations. Fig. 14(a) shows an example where the structure is featured by symmetric and bidirectional edges connecting neurons even belonging to the

Fig. 13 Autoencoder architecture. (a) Simple Autoencoder. (b) Deep Autoencoder.

Fig. 14 General/restricted/deep Boltzmann machine architectures. (a) Boltzmann Machine. (b) Restricted Boltzmann Machine. (c) Deep Boltzmann Machine.

same layer. Within the figure, $\mathbf{x}$ represents the input vector, and $\mathbf{h}$ represents the vector corresponding to the hidden units. The network represents the probabilistic model given by the Gibbs distribution

$$p(\mathbf{x}, \mathbf{h}) = \frac{e^{-E(\mathbf{x}, \mathbf{h})}}{Z}$$

where $E(\mathbf{x}, \mathbf{h})$ represents the “energy” of the network, and Z is a normalization constant. In practice, a Boltzmann machine assumes that each possible configuration of the network is associated with a form of energy, so that low-energy configurations are more probable than high-energy configuration. According to this model, it is possible to devise the probability of the input data

$$p(\mathbf{x}) = \int p(\mathbf{x}, \mathbf{h}) d\mathbf{h}$$

and to interpret the learning process as a way to adjust the interactions between variables in order to make the network more likely to generate the observed data. Notice that the approach is different from the supervised setting explored in the previous sections, where the objective was to learn $p(\mathbf{y} | \mathbf{x})$. In these respect, Boltzmann machines represent a particular case of belief networks, the latter being a directed acyclic graphs composed of stochastic variables (Koller and Friedman, 2009).

In its general formulation, the energy function $E(\mathbf{x}, \mathbf{h})$ expresses the interactions between the variables in the model:

$$E(\mathbf{x}, \mathbf{h}) = \mathbf{x}^T \mathbf{W} \mathbf{h} + \mathbf{h}^T \mathbf{U} \mathbf{h} + \mathbf{x}^T \mathbf{V} \mathbf{x} + \mathbf{b}^T \mathbf{x} + \mathbf{c}^T \mathbf{h}$$

Here, $\mathbf{W}$ represents the weights associated to the inter-layer interactions: that is, w_{ij} is the weight associated with the connection between the input variable x_i and the hidden variable h_j . Similarly, the matrices $\mathbf{U}$ and $\mathbf{V}$ represent the weights of the intra-layer interactions.

In practice, Boltzmann machines are barely used in this general formulation. The most common form assumes that the dependency graph only connections between the layer of hidden and visible variables but not between two variables of the same layer. In practice, the assumption is that the weights $\mathbf{U}$ and $\mathbf{V}$ are fixed to 0. This simpler version is called *Restricted Boltzmann Machine* (RBM) and it is shown in Fig. 14(b). Interestingly, an RBM with binary hidden variable can be interpreted as a stochastic neural network, where for a given hidden node i the conditional probability given the input can be expressed as $p(h_i = 1 | \mathbf{x}) = \sigma(\sum_j w_{ij} x_j + c_i)$. Also, restricting the connectivity only to inter-layer connection makes the learning of a Boltzmann machine easier.

In general, the learning of a (R)BM is accomplished by optimizing the log-likelihood

$$L(\theta; \mathcal{D}) = \sum_i \log p(\mathbf{x}_i)$$

with respect to the parameter set $\theta = \{\mathbf{W}, \mathbf{U}, \mathbf{V}, \mathbf{b}, \mathbf{c}\}$. However, computing such a likelihood or its gradient is computationally intensive. Fortunately, the simplified form of an RBM allows the adoption of sampling methods to approximate the gradient through an efficient algorithm called *Contrastive Divergence* (Hinton, 2002).

Deep Boltzmann Machines (DBM) represent a straightforward generalization of the RBM model (Hinton and Salakhutdinov, 2006; Hinton, 2007; Goodfellow et al., 2013), where several layers of hidden variables are stacked and no connection is established between neurons belonging to the same layer. Fig. 14(c) illustrates the general architecture for these networks. Once again, training these deep networks can be accomplished levelwise, by freezing the previously learned layer and re-applying the learning procedure to the next layer. Interestingly, the network corresponding to a DBM can be extended with an output layer. This way, the weights learned so far can be used as initial weights for the supervised training of the resulting NN.

Closing Remarks

The research on DL has received an extraordinary attention in the last decade. The combination of computational power, new methods for training and new architectures delivered impressive results in a wide range of applications.

Despite these impressive results, there are still several open issues. Tuning these networks is extremely complicated and, although several progress were made by the research in the field, the problem of properly interpreting the behavior of a network and of the hidden units is still open.

This survey did not cover several of these aspects, as well as several other promising directions in the current literature. In particular, reinforcement learning, or adversarial learning are themes of interest which can help improve the performance of these conceptually simple yet extremely powerful models. The interested reader can refer to the references suggested throughout this article as a starting point for continuing the journey into this field.

Introduction

Biostatistics is a branch of applied statistics with applications in many areas of biology including epidemiology, medical sciences, health sciences, educational research and environmental sciences. The principles and methods of statistics, which is the science that deals with the collection, classification, analysis, and interpretation of numerical data for the purpose of data description and decision making, are applied to the biological areas. The first application of statistics appeared during the seventeenth century in political science to describe the various aspects of the affairs of a government or state (hence the term “statistics”). At the same time, the development of probability theory, thanks to the contribution of many mathematicians, such as Blaise Pascal (1623–1662), Pier Fermat (1601–1665), Jacques Bernoulli (1654–1705) and others, has provided the basis for the modern statistics. However, the first scientist to introduce biostatistics concepts was the astronomer and mathematician Adolphe Quetelet (1796–1874), who in his work combined the theory and practical methods of statistics in biological, medical and sociological applications. Later, Francis Galton (1822–1911) tried to solve the problem of heredity on the basis of Darwin’s genetic theories with the statistics. In particular, Galton’s contribution to biology was the application of statistics to the analysis of biological variation, using correlation and regression techniques. For this reason, he has been defined as the father of biostatistics and his methodology has become the basis for the use of statistics in biology. Karl Person (1860–1906) continued in the tradition of Galton’s theory contributing significantly to the field of biometrics, meteorology, theories of social Darwinism and eugenics. The dominant figure in biostatistics during the twentieth century was Ronald Fischer (1890–1962), who used mathematics to combine Mendelian genetics and natural selection. In particular, he developed the analysis of variance (ANOVA) to analyze large amount of biological data. Today, statistics is an active field whose applications touch many aspects of biology and medicine. In particular, we can distinguish two types of statistical approaches, which aim to provide precise conclusions and significant information from a set of data collected during a biological experiment. The first approach is called descriptive statistics and it is used to analyze a collection of data without assuming any underlying structure for such data ([Spriestersbach et al., 2009](#)), while the second one, called inferential statistics, works on the basis of a given structure for the observed data and involves hypothesis testing to draw conclusions about a population when only a part of the data is observed ([Altman and Krzywinski, 2017](#); [Gardner and Altman, 1986](#)). In fact, when a biologist conducts an experiment, he must make sure that the possible conclusions are statistically significant. In addition, the necessity to perform long and laborious arithmetic computations, as part of the statistical analysis of data with the use of computers, has contributed to improve the quality of the data and the interpretation of the results. In fact, the large amount of available statistical software programs, such as the R Project for Statistical Computing, SAS, SPSS and others, have further revolutionized statistical computing in the field of bioinformatics and computational biology.

The aim of this work is to provide statistical concepts that help biologists to correctly prepare experiments, verify conclusions and properly interpret results. We first introduce several descriptive statistical techniques for organizing and summarizing data, and then we discuss some procedures to infer the population parameters using the data contained in a sample that has been drawn from that population. Finally, an illustrative example is analyzed to give a general understanding of the nature and relevance of biostatistics in clinical research.

Statistical Analysis

The descriptive analysis is the starting point in any applied research providing a numerical summary of the collected data ([Spriestersbach et al., 2009](#)). The main steps of a scientific investigation are: collection of data, organization and visualization of data, calculation of descriptive statistics, and interpretation of statistics (see [Fig. 1](#)). Such data are usually available from one or more sources, such as routinely kept records (hospital medical records or hospital accounting records), surveys (questionnaires and interviews), experiments (treatment decision to investigate the effects of the assigned therapy, treatment and control groups), clinical trials (to test efficacy or toxicity of a treatment with respect to control group) and external sources (published reports or data banks). The set of all elements in a data is known as statistical population, while a sample consists of one or more observations extracted from the population. Each member (or element) of the data under investigated is called statistical unit. A statistical variable is each aspect or characteristic of the statistical unit that is considered for the study. A statistical variable can be qualitative or quantitative, depending on whether their nature is countable or not. Quantitative variables can be characterized as discrete or continuous. Examples of discrete variables are the number of daily admissions to a general hospital or the number of decayed, while examples of continuous variables are the diastolic blood pressure, the heart rate, the heights of the adult males or the ages of patients. On the other hand, qualitative or categorical variables involve observations that can be grouped into categories. In particular, these data can be statistically divided into three groups: nominal (when exist a natural ordering among the

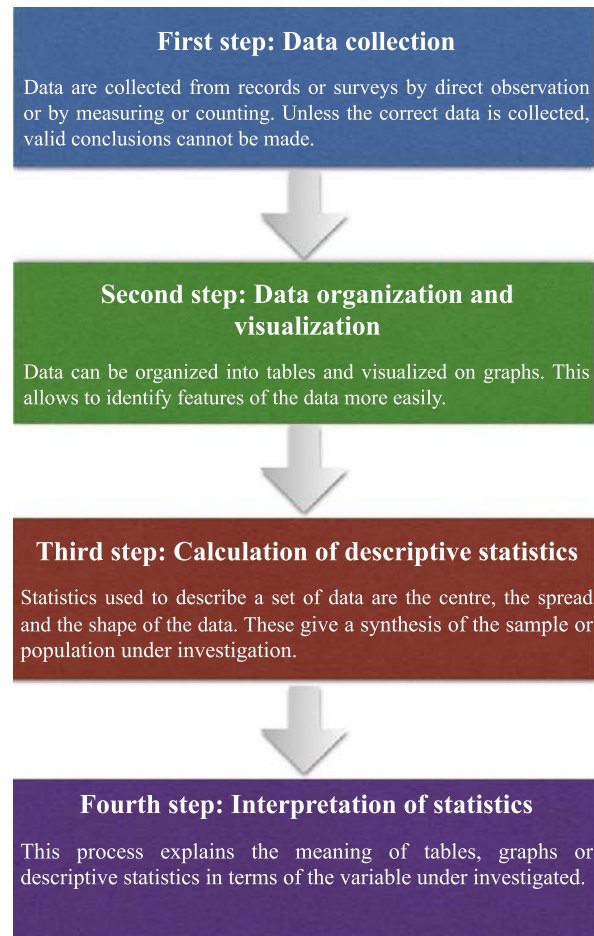

Fig. 1 Main steps of a statistical investigation.

categories), binary or dichotomous (when there are only two possible levels), and ordinal data (when there is a natural order among the categories). Examples of categorical variables involve the sex (male or female), the genotype (AA, Aa, or aa), or the ankle condition (normal, sprained, torn ligament, or broken).

Sometimes in statistics, we use the word measurement (or measurement scale) to categorize and quantify variables. In particular, a measurement is the assignment of numbers to objects or events according to a set of rules. Different measurement scales are distinguished on the relationships assumed to exist between object having different scale values. The most important types of measurement scales are: nominal, ordinal, interval, and ratio. The lowest measurement scale is the nominal scale. It consists of naming observations or classifying them into various mutually exclusive and collectively exhaustive categories. The practice of using numbers to distinguish among the various medical diagnoses constitutes measurement on a nominal scale. When the observations are ranked according to some criterion (from lowest to highest observations), they are said to be measured on an ordinal scale. Convalescing patients may be characterized as unimproved, improved, and much improved. The interval scale is a more sophisticated scale than the nominal and ordinal scale. Here, not only is it possible to order measurements, but also to know the distance between any two measurements. We know that the difference between a measurement of 20 and a measurement of 30 is equal to the difference between measurements of 30 and 40. The ability to do this implies the use of a unit distance and a zero point, both of which are arbitrary. A clear example is the Fahrenheit or Celsius scale. The unit of measurement is the degree of temperature, and the point of comparison is the arbitrarily chosen “zero degrees”, which does not indicate a lack of heat. The interval scale unlike the nominal and ordinal scales is a truly quantitative scale. The highest level of measurement is the ratio scale. This scale is characterized by the fact that equality of ratios as well as equality of intervals may be determined. Fundamental to the ratio scale is a true zero point. The measurement of such familiar traits as height, weight, and length makes use of the ratio scale. Interval and ratio data are sometimes referred to as parametric and nominal and ordinal data are referred to as nonparametric. Parametric means that it meets certain requirements with respect to parameters of the population (normal or bell curve). Parametric data are analyzed using statistical techniques called parametric statistics. Nonparametric data are lacking those same parameters and are investigated by using non-parametric statistics.

Collection, Organization and Visualization of Data

The first step of explaining a biological or biomedical phenomenon is the collection of data under investigated (first step in Fig. 1). Then, the second step is the organization of observed data into tables or data matrix in order to visualize their distribution (second step in Fig. 1). Let N be the number of element or individuals in the population and let X be a random variable assuming the values x_i , for $i = 1, 2, \dots, n$. We denote the number of individuals presenting the value (or characteristic) x_i as n_i . This number n_i is the absolute frequency of the observed value x_i , while the relative frequency f_i of the observed value x_i is the proportion on the total population N of values presenting the value x_i . In symbols, the relative frequency is the ratio

$$f_i = \frac{n_i}{N} \quad (1)$$

for $i = 1, \dots, n$. Note that the sum of the absolute frequencies is equal to the total number of data N and the sum of the relative frequencies is equal to 1:

$$\sum_{i=1}^n n_i = N, \quad \sum_{i=1}^n f_i = 1$$

The observed values x_i , the absolute and relative frequencies are usually organized in tables, called statistical tables or frequency distribution. These tables show the way in which the values of the variable are distributed among the specified characteristics. An example of a univariate statistical table is given in Table 1. When we have a large amount of information, data are grouped into class intervals. A common rule used to choose the number of intervals is to take no fewer than 5 intervals and no more than 15. The better way to decide how many class intervals to employ is to use the Sturges's formula given by $k = 1 + 3.322 \log_{10}(N)$, where k stands for the number of class intervals and N is the number of values in the data set. The width of the class intervals is determined by dividing the range R by k . The range R is given by the difference between the smallest $x_{\min}$ and the largest observation $x_{\max}$ in the data set. The number of values, falling within each class interval, is the absolute frequency n_i , while the proportion of values falling within each class interval is the relative frequency f_i (see Table 2). Starting from the definition of (absolute and relative) frequency distribution, it is possible to calculate the (absolute and relative) cumulative frequency (N_i and F_i , $i = 1, \dots, n$) distribution, which indicates the number of elements in the data set that lie above (or below) a particular value in a data set. For instance, see Tables 1 and 2. Usually, the information contained in these tables can be presented graphically under the form of histograms and cumulative frequency curves. A histogram is a graphical representation of the absolute or relative frequencies for each value of the characteristic or class intervals. It is commonly used for quantitative variables. A cumulative frequency curve is a plot of the number or percentage of individuals falling in or below each value of the characteristic or class intervals. Other types of graphical representations are the pie chart or the bar plot. The first graph is a circular chart divided into sectors, showing the relative magnitudes in frequencies or percentages. The second one, often used to display categorical data, is a

chart with rectangular bars with lengths proportional to the values they represent. They can be plotted vertically or horizontally. Histogram, pie chart and bar plot are graphs very useful for presenting data in a comprehensible way to a statistical and non-statistical audience.

Descriptive Measures

After the organization and visualization of data, several statistical functions can be computed to describe and summarize the set of data (third step in Fig. 1) and to interpret the obtained results (fourth step in Fig. 1). These functions are called descriptive measures or statistics. There are three general types of statistics: measures of central tendency (or location), measures of dispersion (or variability), and measures of symmetry (or shape). The measures of central tendency convey information about the average value of a data. The most commonly used measures of location are the mean, the median, and the mode (Manikandan, 2011a,b; Wilcox and Keselman, 2003). These descriptive measures are called location parameters, because they can be used to designate specific positions on the horizontal axis when the distribution of a variable is graphed. Let X be a random variable and let x be the observed values of the random variable X . The mean is obtained by adding all the values in a population or sample and dividing by the number of values that are observed. We use the Greek letter μ to stand for the population mean, while we use the symbol $\bar{x}$ to define the sample mean:

$$\mu = \frac{1}{N} \sum_{i=1}^N X_i, \quad \bar{x} = \frac{1}{n} \sum_{i=1}^N x_i \quad (2)$$

The value N indicates the population size, the quantity n is the number of observed values in the sample. Similarly, we can compute the mean for (simple and grouped) frequency distributions. An alternative to the mean is the computation of the median. The median is a numerical value that divides the ordered set of values (from lowest to highest value) into two equal parts, such that the number of values equal to or greater than the median is equal to the number of values equal to or less than the median. If the number of values is odd, the median is the middle value of the ordered set of data. If the number of values is even, the median is the mean of the two middle values. In addition, when the median is close to the mean, then we use as statistics the mean, even if the median is usually the better choice. Similarly, we can compute the median for (simple and grouped) frequency distributions. Other location parameters include percentiles or quartiles. These descriptive measures divide the data set into four equal parts each containing 25% of the total observations. The 50th percentile Q_2 is the median. The 25th percentile is the first quartile Q_1 . The 75th percentile is the third quartile Q_3 . Finally, the mode of a variable is the value that occurs most frequently into the data. The mode may not exist, and even if it does, it may not be unique. This happens when the data set has two or more values of equal frequency, which is greater than the other values. The mode is usually used to describe a bimodal distribution. In a bimodal distribution, the taller peak is called the major mode and the shorter one is the minor mode. For continuous data, the mode is the midpoint of the interval with the highest rectangle in the histogram. If the data are grouped into class intervals, then the mode is defined in terms of class frequencies. The mode is used also for describing qualitative data. For example, suppose that the patients in a mental health clinic, during a given year, received one of the following diagnoses: mental retardation, organic brain syndrome, psychosis, neurosis, and personality disorder. The diagnosis, occurring most frequently in the group of patients, is called modal diagnosis. The computational formulas of location measures are shown in Table 3.

Dispersion measures describe the spread or variation present in a set of data. The most important statistics of variability are the range, the variance, the standard deviation and the coefficient of variation (Manikandan, 2011c). The range R is the difference between the largest and smallest value in a set of observations. The variance and the standard deviation are two very popular measures of dispersion.

The variance is defined as the average of the squared differences from the mean, while the standard deviation is a measure of how the data are spread out across the mean. We use the Greek letter σ^2 to indicate the population variance, while we use the symbol s^2 to define the sample variance:

$$\sigma^2 = \frac{1}{N} \sum_{i=1}^N (X_i - \mu)^2, \quad s^2 = \frac{1}{n-1} \sum_{i=1}^N (x_i - \bar{x})^2 \quad (3)$$

The standard deviation is the square root of the variance. The more variation there is into the data, the larger is the standard deviation. The standard deviation is useful as a measure of variation within a given set of data. When two distributions are taken into account and their measures are expressed in different units, compare the two standard deviations may lead to false results. For example, for a certain population we wish to know whether serum cholesterol levels, measured in milligrams per 100 mL, are more variable than body weight, measured in pounds. Therefore, in this case, we use a measure of relative variation rather than absolute variation. Such measure is called coefficient of variation CV , which expresses the standard deviation as a percentage of the mean: it is a unit-free measure. The CV is small if the variation is small and it is unreliable if the mean is near zero. Hence, if we consider two groups, the one with less CV is said to be more consistent.

Another measure of dispersion is the interquartile range (IQR). It is the difference between the third and first quartiles, i.e., $IQR = Q_3 - Q_1$. A large IQR indicates a large amount of variability among the middle 50% of the relevant observations, and a small IQR indicates a small amount of variability among the relevant observations. A useful graph for summarize the information contained in a data set is the box-and-whisker plot. The construction of a box-and-whisker plot makes use of the quartiles of a

Table 3 Summary of the main descriptive statistics used to describe the basic features of the data in a study

Statistics	For population	For sample	For simple frequency distribution	For class frequency distribution
Mean	$\mu = \frac{\sum_{i=1}^N x_i}{N}$ where N is the population size	$\bar{X} = \frac{\sum_{i=1}^n x_i}{n}$ where n is the sample size	$\bar{X} = \frac{\sum_{i=1}^n x_i n_i}{n}$ where n_i is the i th absolute frequency	$\bar{X} = \frac{\sum_{i=1}^n c_i n_i}{n}$ where $c_i = \frac{x_{i+1} + x_i}{2}$ are the central values of each class, for $i = 1, \dots, n$
Median	Odd size: $M_e = \frac{N+1}{2}$ th ordered observation X_i Even size: $M_e = \frac{(\frac{N}{2}) + (\frac{N}{2} + 1)}{2}$ th ordered observation X_i	Odd size: $M_e = \frac{n+1}{2}$ th ordered observation x_i Even size: $M_e = \frac{(\frac{n}{2}) + (\frac{n}{2} + 1)}{2}$ th ordered observation x_i	$M_e = x_i$, such that, $F_i \geq 0.50$ F_i is the i th relative cumulative frequency	$M_e \approx x_i + (x_{i+1} - x_i) \frac{0.5 - F_{i-1}}{F_i - F_{i-1}}$, where $F_i \geq 0.50$ F_i is the i th relative cumulative frequency
Quartiles	$Q_1 = \frac{N+1}{4}$ th ordered observation X_i $Q_2 = M_e$ $Q_3 = \frac{3(N+1)}{4}$ th ordered observation X_i	$Q_1 = \frac{n+1}{4}$ th ordered observation x_i $Q_2 = M_e$ $Q_3 = \frac{3(n+1)}{4}$ th ordered observation x_i	$Q_1 = x_i$, such that, $F_i \geq 0.25$ $Q_2 = M_e$ $Q_3 = x_i$, such that, $F_i \geq 0.75$ F_i is the i th relative cumulative frequency	$Q_1 \approx x_i + (x_{i+1} - x_i) \frac{0.25 - F_{i-1}}{F_i - F_{i-1}}$, where $F_i \geq 0.25$ $Q_2 = M_e$ $Q_3 \approx x_i + (x_{i+1} - x_i) \frac{0.75 - F_{i-1}}{F_i - F_{i-1}}$, where $F_i \geq 0.75$
Mode	$M_o = x_i$ is the value that occurs most frequently in the data	$M_o = x_i$ is the value that occurs most frequently in the data	$M_o = \{x_i : n_i = \max\}$, where n_i is the i th absolute frequency	$m_c = \{x_i - x_{i+1} - x_i : h_i = \max\}$, where $h_i = \frac{n_i}{x_{i+1} - x_i}$ is the intensity class $M_o \approx \frac{x_i + x_{i+1}}{2}$
Range	$R = X_{\max} - X_{\min}$	$R = X_{\max} - X_{\min}$	$R = X_{\max} - X_{\min}$	$R = X_{\max} - X_{\min}$
Interquartile range	$IQR = Q_3 - Q_1$	$IQR = Q_3 - Q_1$	$IQR = Q_3 - Q_1$	$IQR = Q_3 - Q_1$
Variance	$\sigma^2 = \frac{\sum_{i=1}^N (x_i - \mu)^2}{N}$	$s^2 = \frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n-1}$	$s^2 = \frac{\sum_{i=1}^n (x_i - \bar{x})^2 n_i}{n-1}$	$s^2 = \frac{\sum_{i=1}^n (c_i - \bar{x})^2 n_i}{n-1}$
Deviazione standard	$\sigma = \sqrt{\sigma^2}$	$s = \sqrt{s^2}$	$s = \sqrt{s^2}$	$s = \sqrt{s^2}$
Correlation of variation	$CV = \frac{\sigma}{\mu} \times 100$	$CV = \frac{s}{\bar{x}} \times 100$	$CV = \frac{s}{\bar{x}} \times 100$	$CV = \frac{s}{\bar{x}} \times 100$
Skewness	$\Gamma_1 = \frac{1}{N\sigma^3} \sum_{i=1}^N (x_i - \mu)^3$	$\gamma_1 = \frac{\frac{\sqrt{n}}{(n-1)\sqrt{n-1}s^3} \sum_{i=1}^n (x_i - \bar{x})^3}{n_i}$	$\gamma_1 = \frac{\frac{\sqrt{n}}{(n-1)\sqrt{n-1}s^3} \sum_{i=1}^n (x_i - \bar{x})^3 n_i}{n_i}$	$\gamma_1 = \frac{\frac{\sqrt{n}}{(n-1)\sqrt{n-1}s^3} \sum_{i=1}^n (c_i - \bar{x})^3 n_i}{n_i}$
Kurtosis	$\Gamma_2 = \frac{1}{N\sigma^4} \sum_{i=1}^N (x_i - \mu)^4$	$\gamma_2 = \frac{\frac{n(n+1)}{(n-1)(n-2)(n-3)s^4} \sum_{i=1}^n (x_i - \bar{x})^4}{n_i}$	$\gamma_2 = \frac{\frac{n(n+1)}{(n-1)(n-2)(n-3)s^4} \sum_{i=1}^n (x_i - \bar{x})^4 n_i}{n_i}$	$\gamma_2 = \frac{\frac{n(n+1)}{(n-1)(n-2)(n-3)s^4} \sum_{i=1}^n (c_i - \bar{x})^4 n_i}{n_i}$

data set (see Fig. 2). An outlier is an observation whose value either exceeds the value of the third quartile by a magnitude greater than $1.5 \times (IQR)$ or is less than the value of the first quartile by a magnitude greater than $1.5 \times (IQR)$. Similarly, we can compute the (simple and grouped) dispersion measures for frequency distributions. The computational formulas of variability measures are shown in Table 3.

An attractive property of a data distribution occurs when the mean, median, and mode are all equal. The well-known “bell-shaped curve” is a graphical representation of a distribution for which the mean, median, and mode are equal among them. Much statistical inference is based on this distribution called normal distribution (see Fig. 3). Generally, a data distribution can be classified on the basis of their form (symmetric or asymmetric). A symmetric distribution is a type of distribution where the left side of the distribution mirrors the right side (see Fig. 3). When the left half and right half of the graph of a distribution are not mirror images of each other, the distribution is asymmetric. In this case, the distribution is said to be skewed. In other words,

Fig. 2 Boxplot or box plot whisker diagram.

Fig. 3 Normal or Gaussian distribution with mean $\mu = 5$ and standard deviation $\sigma = 2$.

Fig. 4 Positively Skewed Distribution (to the right) and negatively Skewed Distribution (to the left).

mean, median and mode occur at different points of the distribution. In particular, there are two kinds of skewness. The distribution is said to be left-skewed (or negatively skewed) if the distribution appears to be skewed to the left, i.e. its mean is less than its mode. On the contrary, the distribution is said to be right-skewed (positively skewed) if the distribution is skewed to the right, i.e., its mean is greater than its mode. Most computer statistical packages (e.g., The R Project for Statistical Computing) include this statistic as part of a standard printout. A value of skewness > 0 indicates positive skewness and a value of skewness < 0 indicates negative skewness (see Fig. 4). As skewness involves the third moment of the distribution, kurtosis involves the fourth moment. Usually, kurtosis is quoted in the form of excess kurtosis (kurtosis relative to normal distribution kurtosis). Excess kurtosis is simply kurtosis less 3. In fact, kurtosis for a standard normal distribution is equal to three. There are three different ways to define the kurtosis. A distribution with excess kurtosis equal to zero (and kurtosis exactly 3) is called *mesokurtic*, or *mesokurtotic*. A distribution with positive excess kurtosis (and $\gamma_2 > 3$) is called *leptokurtic*, or *leptokurtotic*. A distribution with negative excess kurtosis (and $\gamma_2 < 3$) is called *platykurtic*, or *platykurtotic*. For instance, see Fig. 5. In terms of shape, a leptokurtic distribution has fatter tails while a platykurtic distribution has thinner tails. The computational formulas of skewness and kurtosis are shown in Table 3.

Inferential Statistics

Statistical inference is the procedure by which we obtain a conclusion about a population on the basis of the information contained in a sample drawn from that population. The basic assumption in statistical inference is that each element, within the population of interest, has the same probability of being included in a specific sample. Therefore, the knowledge of the probability distribution of a random variable provides the clinician and researcher with a powerful tool for summarizing and describing a set of data and for reaching conclusions about a population of data on the basis of a sample drawn from that population. In this section, we discuss two general areas of statistical inference, estimation and hypothesis testing, used to infer the population parameters under the assumption that the sample estimates follow the normal or Gaussian distribution. These types of statistical inference procedures are classified as parametric statistics.

Continuous Probability Distributions

To understand the nature of the distribution of a continuous random variable, we consider the probability density function which is the area under a smooth curve between any two points a and b , i.e., the definite integral between a and b . Thus, the probability of a continuous random variable to assume values between a and b is denoted by $P(a < X < b)$. The graph of probability density function is shown in Fig. 6.

The normal distribution is the most important continuous probability distribution in statistics. It describes well the distribution of random variables that arise in practice, such as the heights, weights, blood pressure, body mass, etc. Let X be a random variable normally distributed, the probability density function of X is given by

$$f(x) = \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right), \quad -\infty < x < +\infty \quad (4)$$

Fig. 5 Kurtosis distributions: a distribution with kurtosis equal to zero is called *mesokurtic*, or *mesokurtotic* (red line); a distribution with positive kurtosis is called *leptokurtic*, or *leptokurtotic* (blue line); a distribution with negative kurtosis is called *platykurtic*, or *platykurtotic* (gold line).

Fig. 6 Graph of a continuous distribution showing area between a and b . The probability of a continuous random variable to assume values between a and b is denoted by $P(a < X < b)$.

where the parameters μ and σ^2 are the mean and variance of X , respectively. Generally, we write $X \sim N(\mu, \sigma^2)$. Which means that X follows the normal distribution (or X is normally distributed) with mean μ , and variance σ^2 . The graph of the normal distribution produces the familiar bell-shaped curve shown in [Fig. 7](#). It is symmetrical about its mean μ . Mean, median and mode are equal. The total area under the curve above the x -axis is one square unit. In particular, the 68% of observations lie between $(\mu \pm \sigma)$, 95% of observations lie between $(\mu \pm 2\sigma)$ and 99.7% of observations lie between $(\mu \pm 3\sigma)$. For instance, see [Fig. 8](#). The normal distribution is completely determined by the parameters μ and σ^2 . Different values of μ and σ shift the graph of the distribution along the x -axis. Different values of σ determine the degree of flatness or peakedness of the graph of the distribution. Because of the characteristics of these two parameters, μ is often referred to as a location parameter and σ is often referred to as a shape parameter. The normal distribution with mean $\mu=0$ and $\sigma^2=1$ is called standard normal distribution. It is obtained from [Eq. \(5\)](#) by setting

$$z = \frac{(x - \mu)}{\sigma}$$

This value is called z -transformation (or z -score). Hence, the probability density function of the standard normal distribution is

$$f(x) = \frac{1}{\sqrt{2\pi}} \exp^{-\frac{z^2}{2}}, -\infty < x < +\infty \quad (5)$$

Fig. 7 Normal or Gaussian distribution with mean μ and standard deviation σ .

Fig. 8 Standard deviation and coverage. About 68% of values drawn from a normal distribution are within one standard deviation away from the mean; about 95% of the values lie within two standard deviations; and about 99.7% are within three standard deviations.

The graph of the standard normal distribution is shown in [Fig. 9](#). The probability of the random variables z between two points (or to the left/right of a given z -score) on the z -axis is the areas located under the curve of the standard normal distribution. The probability of z can be calculated by using standard normal distribution tables well known in literature.

Three important distributions related to the normal distribution are: Chi-square distribution, t distribution and F distribution. Let $X_1, X_2, \dots, X_m$ be m independent random variables having standard normal distribution, i.e., $X_i \sim N(0,1)$, the new random variable

$$Z = \sum_{i=1}^m X_i^2 \sim \chi_m^2$$

follows a Chi-Square distribution with m degrees of freedom (i.e., the number of random variables). Its mean is m , and its variance is $2m$. The probability density function of Z is given by

$$f(z) = \frac{1}{2^{\frac{m}{2}} \Gamma(\frac{m}{2})} \exp^{-\frac{z}{2}} z^{\frac{m}{2}-1}, \quad 0 < z < +\infty \quad (6)$$

where the gamma function Γ is the integral

$$\Gamma(x) = \int_0^{\infty} \gamma^{x-1} e^{-\gamma} d\gamma, \quad x > 0$$

Fig. 9 Standard normal distribution with mean $\mu=0$ and standard deviation $\sigma=1$.

Note that as the degrees of freedom increase, the chi-square curve approaches a normal distribution. The graph of the Chi-squares X^2 distribution is shown in [Fig. 10](#).

The Student's t distribution is a probability distribution that is used to estimate population parameters when the sample size is small and/or when the population variance is unknown. Let Z be a random variable with standard normal distribution, i.e., $Z \sim N(0,1)$, and let V be a random variable having a Chi-square distribution with m degrees of freedom, i.e., $V \sim \chi_m^2$. Assume further that Z and V are independent. Define a new random variable T by

$$T = \frac{Z}{\sqrt{V/m}} \sim T_m$$

called Student t distribution with m degrees of freedom. The probability density function of the t distribution with m degrees of freedom is

$$f(t) = \frac{\Gamma(\frac{m+1}{2})}{\sqrt{\pi m} \Gamma(\frac{m}{2})} \left(1 + \frac{t^2}{m}\right)^{-\frac{m+1}{2}}, -\infty < t < +\infty \quad (7)$$

It is symmetrical about the mean equal to zero. It has a variance greater than 1, but the variance approaches 1 as the sample size becomes large, i.e., $\text{Var}(T) = \frac{m}{m-2}$. The shape of the t -distribution curve depends on the number of degrees of freedom. Compared to the normal distribution, the t distribution is less peaked in the center and has thicker tails. Finally, the t distribution approaches the standard normal distribution as m tends to infinity. The graph of the Student t distribution is shown in [Fig. 11](#).

Let U and V be independent chi-square random variables with m and n degrees of freedom, respectively. The variable

$$F = \frac{U/m}{V/n} \sim F_{m,n}$$

follows the Fisher F distribution with numerator degree of freedom m and denominator degree of freedom n . The probability density function of the F distribution is

$$f(x) = \frac{\Gamma(\frac{m+n}{2})}{\Gamma(\frac{m}{2})\Gamma(\frac{n}{2})} \left(\frac{m}{n}\right)^{\frac{m}{2}} x^{\frac{n}{2}-1} \left(1 + \frac{m}{n}x\right)^{-\frac{(m+n)}{2}}, 0 < x < +\infty \quad (8)$$

Then, the mean is $E(X) = \frac{n}{n-2}$ and the variance $\text{Var}(X) = \frac{2n^2(m+n-2)}{m(n-2)^2(m-4)}$. In general, the F distribution is skewed to the right. The graph of the Fisher F distribution is shown in [Fig. 12](#). The X^2, t, F distributions, like the standard normal, has been extensively tabulated.

Estimation

The estimation process consists of estimate sample statistics in order to give an approximation of the corresponding parameters of the population from which the sample is drawn. For example, we suppose that the administrator of a hospital is interested in the

Chi-square distributions

Fig. 10 Chi-square distribution for different degrees of freedom.

mean age of patients admitted to the hospital during a given year. He decides to examine only a sample of the records to conduct his analysis in order to determine a mean age estimation of all patients admitted to the hospital during the year. This statistic is an estimation of the corresponding population mean. Typically, we expect the estimate to differ by some amount from the parameter it estimates.

For each of the population parameters, we can compute two types of estimate: a point estimate and an interval estimate. A point estimate is a single numerical value used to estimate the corresponding population parameters, while an interval estimate is an interval that, with a specified degree of confidence, most likely includes the parameters being estimated ([Gardner and Altman, 1986](#)). For example, let X be a random variable that follows the normal distribution with mean μ , and variance σ^2 . The computed sample mean $\bar{x}$ is a point estimator of the population mean μ . Similarly, the computed sample variance s^2 is a point estimation of the of the population variance σ^2 . Interval estimation is an alternative procedure to point estimation. It consists to replace the point estimator of the population parameter by using a statistic that allows to calculate an interval of the parameter space. Let θ be the parameter space and let X be a random variable from a distribution that belongs to a family of distributions with a parameter $\theta \in \theta$. A confidence interval (CI) is an interval composed by two numerical values, called lower and upper limit, that with a specified degree of confidence $\alpha \in (0,1)$ includes the unknown parameter θ . In other words, it is an interval that with probability $1 - \alpha$, include the unknown parameter θ . The probability $1 - \alpha$ is called the confidence coefficient and represents the area under the probability distribution between the two limits of the CI. Usually, $1 - \alpha$ is taken to be 0.90, 0.95 or 0.99. To construct a confidence interval CI, we generally consider the following steps:

1. the sample statistic is identified to estimate a population parameter θ (for example, the population mean or the population variance);
2. the confidence level $1 - \alpha$ is fixed to compute the margin of error, i.e., the product between the critical value (which is a term that splits the area under the probability distribution in two regions) and the standard deviation;
3. the limits of the confidence interval are determined as follow.

$$\text{CI} = \text{sample statistic} \pm \text{margin of error} \quad (9)$$

In particular, when X is a random variable normally distributed with mean μ , and variance σ^2 , we can construct different type of CI for the mean μ with known or unknown variance σ^2 .

Fig. 11 Student distribution for different degree of freedom.

Confidence interval CI for the population mean μ

When the variance σ^2 is known, the statistic used to construct a $100(1 - \alpha)$ confidence interval CI for the population mean μ is the quantity

$$z = \frac{\bar{x} - \mu}{\sigma/\sqrt{n}} \sim N(0, 1) \quad (10)$$

where σ is the known population standard deviation. Then, an interval estimate for μ is expressed as

$$\left(\bar{x} - z_{\alpha/2} \frac{\sigma}{\sqrt{n}}, \bar{x} + z_{\alpha/2} \frac{\sigma}{\sqrt{n}} \right) \quad (11)$$

where the critical value, denoted by $z_{\alpha/2}$, is the value of z to the left of which lies $-\alpha/2$ and to the right of which lies $\alpha/2$ of the area under its curve, i.e., $P(Z \geq |z_{\alpha/2}|) = \frac{\alpha}{2}$ with $Z \sim N(0, 1)$. For instance, see Fig. 13. When the variance σ^2 is unknown and the sample size n is large ($n > 30$), we consider the Student's t distribution. In this case, the statistic used to construct a $100(1 - \alpha)$ confidence interval CI for the population mean μ is given by

$$t = \frac{\bar{x} - \mu}{s/\sqrt{n}} \sim T_{(n-1)} \quad (12)$$

where s is the sample standard deviation to replace σ in Eq. (11). This statistics follows a Student's distribution with $n - 1$ degrees of freedom. An interval estimate for μ is expressed as

$$\left(\bar{x} - t_{\alpha/2, n-1} \frac{s}{\sqrt{n}}, \bar{x} + t_{\alpha/2, n-1} \frac{s}{\sqrt{n}} \right) \quad (13)$$

where the critical value, denoted by $t_{\alpha/2, n-1}$, is the value of t to the left of which lies $-\alpha/2$ and to the right of which lies $\alpha/2$ of the area under its curve, i.e. $P(T \geq |t_{\alpha/2, n-1}|) = \frac{\alpha}{2}$ with $T \sim T_{(n-1)}$. For instance, see Fig. 14.

Confidence interval CI for the difference between the population means $\mu_1 - \mu_2$

Sometimes we are interested in estimating the difference between two population means. From each of the populations an independent random sample is drawn and, from the data of each, the sample means $\bar{x}_1$ and $\bar{x}_2$ respectively, are computed.

Fisher distributions

Fig. 12 Fisher distribution for different degree of freedom.

Critical regions – Standard normal distribution

Fig. 13 Critical regions for the standard normal distribution.

Critical regions – Student t distribution

Fig. 14 Critical regions for the Student distribution.

An unbiased estimate of the difference between the population means, $\mu_1 - \mu_2$, is the difference between the sample means, $\bar{x}_1 - \bar{x}_2$. The variance of the estimator is $\left(\frac{\sigma_1^2}{n}\right) + \left(\frac{\sigma_2^2}{m}\right)$, where n and m are the sample sizes. The statistic used to construct a $100(1 - \alpha)$ confidence interval CI for the difference between the population means, $\mu_1 - \mu_2$ is

$$z = \frac{(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)}{\sqrt{\frac{\sigma_1^2}{n} + \frac{\sigma_2^2}{m}}} \sim N(0, 1) \quad (14)$$

Hence, a confidence interval CI for $\mu_1 - \mu_2$ is given by

$$\left((\bar{x}_1 - \bar{x}_2) - z_{\alpha/2} \sqrt{\frac{\sigma_1^2}{n} + \frac{\sigma_2^2}{m}}, (\bar{x}_1 - \bar{x}_2) + z_{\alpha/2} \sqrt{\frac{\sigma_1^2}{n} + \frac{\sigma_2^2}{m}} \right) \quad (15)$$

where the critical value, denoted by $z_{\alpha/2}$, is the value of z to the left of which lies $-\alpha/2$ and to the right of which lies $\alpha/2$ of the area under its curve, i.e. $P(Z \geq |z_{\alpha/2}|) = \frac{\alpha}{2}$ with $Z \sim N(0, 1)$. For instance, see Fig. 13. An investigation of a confidence interval CI for the difference between population means provides information that is helpful in deciding whether or not it is likely that the two population means are equal. When the constructed interval does not include zero, we say that the interval provides evidence that the two population means are not equal. When the interval includes zero, we say that the population means may be equal. When population variances are unknown, we use the t distribution to estimate the difference between two population means with a confidence interval CI. We assume that the two sampled populations are normally distributed. With regard to the population variances, we distinguish two cases: (1) the population variances are equal, and (2) the population variances are not equal. Let us consider each situation separately. If the population variances are equal, the two sample variances that we compute from two independent samples are estimates of the same quantity, the common variance. This estimation is called pooled estimate and it is obtained by computing the weighted average of the two sample variances. Each sample variance is weighted by its degrees of freedom. The pooled estimate is given by the formula

$$s_p^2 = \frac{(n-1)s_1^2 + (m-1)s_2^2}{n+m-2} \quad (15)$$

where n and m are the sample sizes. The statistic used to construct a $100(1 - \alpha)$ confidence interval CI for the difference between the population means, $\mu_1 - \mu_2$ is

$$z = \frac{(\bar{x}_1 - \bar{x}_2) - (\mu_1 - \mu_2)}{s_p \sqrt{\frac{1}{n} + \frac{1}{m}}} \sim T_{(n+m-2)} \quad (16)$$

Hence, a confidence interval CI for $\mu_1 - \mu_2$, when population variances are unknown and equal, is given by

$$\left((\bar{x}_1 - \bar{x}_2) - t_{\alpha/2; n+m-2} s_p \sqrt{\frac{1}{n} + \frac{1}{m}}, (\bar{x}_1 - \bar{x}_2) + t_{\alpha/2; n+m-2} s_p \sqrt{\frac{1}{n} + \frac{1}{m}} \right) \quad (17)$$

where the critical value, denoted by $t_{\alpha/2; n+m-2}$, is the value of t to the left of which lies $-\alpha/2$ and to the right of which lies $\alpha/2$ of the area under its curve, i.e., $P(T \geq |t_{\alpha/2; n+m-2}|) = \frac{\alpha}{2}$ with $T \sim T_{(n+m-2)}$.

If the population variances are not equal, the solution, proposed by Cochran (1964) consists of computing the reliability factor, $t'_{\alpha/2}$ by the following formula:

$$t'_{\alpha/2} = \frac{w_1 t_1 + w_2 t_2}{w_1 + w_2}$$

where $w_1 = \frac{s_1^2}{n}$, $w_2 = \frac{s_2^2}{m}$, $t_1 - t_{\alpha/2}$ for $n-1$ degrees of freedom, and $t_2 - t_{\alpha/2}$ for $m-1$ degrees of freedom. Hence, an approximate a $100(1 - \alpha)$ confidence interval CI for the difference between the population means, $\mu_1 - \mu_2$ is given by

$$\left((\bar{x}_1 - \bar{x}_2) - t'_{\alpha/2} s_p \sqrt{\frac{1}{n} + \frac{1}{m}}, (\bar{x}_1 - \bar{x}_2) + t'_{\alpha/2} s_p \sqrt{\frac{1}{n} + \frac{1}{m}} \right) \quad (18)$$

Confidence interval CI for a population proportion

Many questions of interest to the health science are related to population proportions. For example, the proportion of patients who receive a particular type of treatment, or the proportion of some population who has a certain disease or the proportion of a population who is immune to a certain disease. In this case, we consider the binomial distribution frequently used to model the number of successes p in a sample of size n drawn with replacement from a population of size n . Hence, the binomial distribution is characterized by two parameters, n and p . When the sample size is large, the distribution of sample proportions is approximately normally distributed by virtue of the central limit theorem. The mean of the distribution, $\mu_{\hat{p}}$, that is, the average of all the possible sample proportions, is equal to the true population proportion, p , and the variance of the distribution, $\sigma_{\hat{p}}^2$, is equal to $\frac{p(1-p)}{n}$. To estimate the population proportion, we compute the sample proposition $\hat{p}$. This sample proportion is used as the point estimator of the population proportion. In particular, when both np and $n(1-p)$ are greater than 5, we can say that the sampling distribution of $\hat{p}$ is approximately normally distributed with mean $\mu_{\hat{p}} = p$. Hence, the statistic used to construct a $100(1 - \alpha)$ confidence interval

CI for the population proportion p is given by

$$z = \frac{p - \hat{p}}{\sqrt{\frac{\hat{p}(1-\hat{p})}{n}}} \sim N(0, 1) \quad (19)$$

A confidence interval CI for the population proportion p is

$$\left(\hat{p} - z_{\alpha/2} \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}, \hat{p} + z_{\alpha/2} \sqrt{\frac{\hat{p}(1-\hat{p})}{n}} \right) \quad (20)$$

where the critical value, denoted by $z_{\alpha/2}$, is the value of z to the left of which lies $-\alpha/2$ and to the right of which lies $\alpha/2$ of the area under its curve, i.e., $P(Z \geq |z_{\alpha/2}|) = \frac{\alpha}{2}$ with $Z \sim N(0,1)$. For instance, see Fig. 13.

Confidence interval CI for the difference between two population proportions

Often there are two population proportions in which we are interested and we desire to assess the probability associated with a difference in proportions computed from samples drawn from each of these populations. The relevant sampling distribution is the distribution of the difference between the two sample proportions. If independent random samples of size n and m are drawn from two populations of dichotomous variables where the proportions of observations with the characteristic of interest in the two populations are p_1 and p_2 , respectively, the distribution of the difference between sample proportions, $\hat{p}_1 - \hat{p}_2$, is approximately normal with mean and variance equal to

$$\mu_{\hat{p}_1 - \hat{p}_2} = p_1 - p_2, \text{ and } \sigma_{\hat{p}_1 - \hat{p}_2}^2 = \frac{p_1(1-p_1)}{n} + \frac{p_2(1-p_2)}{m}$$

respectively, when n and m are large (i.e., np_1 , mp_2 , $n(1-p_1)$ and $m(1-p_2)$ are greater than 5). Hence, an unbiased point estimator of the difference between two population proportions is provided by the difference between sample proportions, $\hat{p}_1 - \hat{p}_2$. The statistic used to construct a $100(1-\alpha)$ confidence interval CI for the difference between two population proportions $p_1 - p_2$ is

$$z = \frac{(\hat{p}_1 - \hat{p}_2) - (p_1 - p_2)}{\sqrt{\frac{\hat{p}_1(1-\hat{p}_1)}{n} + \frac{\hat{p}_2(1-\hat{p}_2)}{m}}} \sim N(0, 1) \quad (21)$$

A confidence interval CI for $p_1 - p_2$ is given by

$$\left((\hat{p}_1 - \hat{p}_2) - z_{\alpha/2} \sqrt{\frac{\hat{p}_1(1-\hat{p}_1)}{n} + \frac{\hat{p}_2(1-\hat{p}_2)}{m}}, (\hat{p}_1 - \hat{p}_2) + z_{\alpha/2} \sqrt{\frac{\hat{p}_1(1-\hat{p}_1)}{n} + \frac{\hat{p}_2(1-\hat{p}_2)}{m}} \right) \quad (22)$$

where the critical value, denoted by $z_{\alpha/2}$, is the value of z to the left of which lies $-\alpha/2$ and to the right of which lies $\alpha/2$ of the area under its curve, i.e., $P(Z \geq |z_{\alpha/2}|) = \frac{\alpha}{2}$ with $Z \sim N(0,1)$. For instance, see Fig. 13.

Confidence interval CI for the population variance σ^2

The statistic used to construct a $100(1-\alpha)$ confidence interval CI for the population variance σ^2 is

$$\chi^2 = \frac{(n-1)s^2}{\sigma^2} \sim \chi^2(n-1) \quad (23)$$

This statistics follows a chi-square χ^2 distribution with $n-1$ degrees of freedom. An interval estimate for σ^2 is expressed as

$$\left(\frac{(n-1)s^2}{\chi_{1-\alpha/2; n-1}^2}, \frac{(n-1)s^2}{\chi_{\alpha/2; n-1}^2} \right) \quad (24)$$

where s is the sample variance and $\chi_{1-\alpha/2; n-1}^2$ and $\chi_{\alpha/2; n-1}^2$ are the values from the χ^2 table to the left and right of which, respectively, lies $\alpha/2$ of the area under the curve, i.e., $P(Y \leq \chi_{1-\alpha/2; n-1}^2) = 1 - \frac{\alpha}{2}$ and $P(Y \geq \chi_{\alpha/2; n-1}^2) = \frac{\alpha}{2}$ with $Y \sim \chi_{(n-1)}^2$. For instance, see Fig. 15. If we take the square root of each term in Eq. (23), we have the confidence interval for σ , the population standard deviation.

Fig. 15 Critical regions for the Chi-square distribution.

Critical regions – Fisher distribution

Fig. 16 Critical regions for the Fisher distribution.

Confidence interval CI for the ratio of the variances of two normally distributed populations

Generally, we consider the ratio σ_1^2/σ_2^2 to compare the variances of two normally distributed populations. If two variances are equal, their ratio will be equal to 1. We usually will not know the variances of populations of interest, and, consequently, any comparisons we make will be based on sample variances. In other words, we may wish to estimate the ratio of two population variances. The assumptions are that s_1^2 and s_2^2 are computed from independent samples of size n and m respectively, drawn from two normally distributed populations. The variance s_1^2 is designed as the larger of the two sample variances. Hence, the statistic used to construct a $100(1-\alpha)$ confidence interval CI for the ratio of the variances of two normally distributed populations is

$$F = \frac{s_1^2/\sigma_1^2}{s_2^2/\sigma_2^2} \sim F_{(n-1; m-1)} \quad (25)$$

This statistic follows a F distribution depending on two-degrees-of-freedom values, one corresponding to the value of $n-1$ used in computing s_1^2 and the other corresponding to the value of $m-1$ used in computing s_2^2 . These are usually referred to as the numerator degrees of freedom and the denominator degrees of freedom. An interval estimate for the ratio σ_1^2/σ_2^2 is expressed as

$$\left(\frac{s_1^2/s_2^2}{F_{1-\alpha/2; n-1; m-1}}, \frac{s_1^2/s_2^2}{F_{\alpha/2; n-1; m-1}} \right) \quad (26)$$

where $F_{1-\alpha/2; n-1; m-1}$ and $F_{\alpha/2; n-1; m-1}$ are the values from the F table to the left and right of which, respectively, lies $\alpha/2$ of the area under the curve i.e., $P(F \leq F_{1-\alpha/2; n-1; m-1}) = 1 - \frac{\alpha}{2}$ and $P(Y \geq F_{\alpha/2; n-1; m-1}) = \frac{\alpha}{2}$ with $F \sim F_{(n-1; m-1)}$. For instance, see Fig. 16.

Note that the tables of all the critical values can be used for both one-sided (lower and upper) and two-sided tests with specific values of α .

Hypothesis Testing

The aim of hypothesis testing is to aid the clinician and researcher in reaching a conclusion concerning a population by examining a sample from that population. Interval estimation, discussed in the preceding section, and hypothesis testing are based on similar concepts. In fact, confidence intervals can be used to obtain the same conclusions that are reached through the use of hypothesis tests. There are two statistical hypotheses involved in hypothesis testing: the null hypothesis and the alternative hypothesis. The null hypothesis is the hypothesis to be tested and it is designated by the symbol H_0 . The null hypothesis is the hypothesis of no difference (or equality, either $=$, $\leq$, or $\geq$), since it is a statement of agreement with conditions supposed to be true in the population under investigated. Consequently, the conclusion that the researcher is seeking to reach is to reject the null hypothesis. If the null hypothesis is not rejected, we conclude that the data not provide sufficient evidence that the null hypothesis is not in reality true. The alternative hypothesis, designed by the symbol H_1 , is the statement that researchers hope to be true. In other words, it is the hypothesis of effect or real difference. Based on the sample data, the test determines whether to reject the null hypothesis. In particular, we can follow two types of decisional strategies. The first approach is based on the computation of test statistic, the second one is called p -value approach (Altman and Krzywinski, 2017; Gardner and Altman, 1986). All possible values that the test statistic can assume are arranged on the horizontal axis of the probability distribution and are divided into two regions: the rejection region and non rejection region. The values of the test statistic forming the rejection region are those values that are less likely to occur if the null hypothesis is true, while the values making up the acceptance region are more likely to occur if the null hypothesis is true. The decision rule tells us to reject the null hypothesis if the value of the test statistic that we compute from the sample falls in the rejection region or not. The decision to reject or accept the null hypothesis is based on the level of significance α . A computed value of the test statistic that falls in the rejection region is said to be significant. Generally, a small value of α is selected to make the probability of rejecting a true null hypothesis small. The more frequently values used for α are 0.01, 0.05, and 0.10. The relationship between the (unknown) reality if the null hypothesis is true or not and the decision to accept or reject the null hypothesis is shown in Table 4. The error committed when a true null hypothesis is rejected is called the type I error. The type II error is the error committed when a false null hypothesis is not rejected. The probability of committing a type II error is designated by β . The II error is know as the statistical power, which is the ability of a test to detect a true effect, i.e., reject the null hypothesis if the alternative hypothesis is true. The second strategy is based on the concept of p -value, which is the probability that the computed test statistic is at least as extreme as a specified value of the test statistic when the null

Table 4 Conditions under which type I and type II errors may be committed

Decision rules	The truth	
	H_0 true	H_1 true
Accept H_0	Correct decision	Type II error
Reject H_0	Type I error	Correct decision

hypothesis is true. Thus, the p -value is the smallest value (typical less than 5%) for which we reject a null hypothesis. To calculate the p -value, we first calculate the value of the test statistic, and then, using the known distribution of the test statistic, calculate the p -value. Note that the probability of rejecting a true null hypothesis is the significance level α , we conclude that, if the p -value is less than (or equal to) α , then the null hypothesis is rejected, while, if the p -value is greater than α , then the null hypothesis is not rejected (or accepted). For instance, see [Tables 5](#) and [6](#).

Non-Parametric Statistics

In this section, we explore the most common non-parametric techniques used when the underlying assumptions of traditional hypothesis tests are violated. These statistical procedures allow for the testing of hypotheses that are not statements about population parameter values and are applied when the form of the sampled population is unknown.

Wilcoxon signed-rank test for location

Suppose to test a null hypothesis about a population mean, but neither z nor t is an appropriate test statistic because the sampled population does not follow or approximate a normal distribution ([Wilcoxon, 1945](#)). When confronted with such a situation we use a non-parametric statistical procedure called Wilcoxon signed-rank test for location. It makes use of the magnitudes of the differences between measurements and a hypothesized location parameter rather than just the signs of the differences. The Wilcoxon test is based on the following assumptions about the data: (i) the sample is random; (ii) the variable is continuous; (iii) the population is symmetrically distributed about its mean μ ; (iv) the measurement scale is at least interval. After the formulation of null mean H_0 and alternative hypothesis H_1 ,

$$H_0 : \mu = \mu_0 (\leq, \geq) \text{ vs } H_1 : \mu \neq \mu_0 (>, <)$$

we perform the Wilcoxon test when the population mean μ_0 is unknown.

1. Subtract the Hypothesized Mean μ_0 from Each Observation x_i to Obtain

$$d_i = x_i - \mu_0.$$

If any x_i is equal to the mean, so that, $d_i = 0$, eliminate that d_i from the calculations and reduce n accordingly.

2. Rank the usable d_i from the smallest to the largest without regard to the sign of d_i . That is, consider only the absolute value of the d_i , designated $|d_i|$, when ranking them. If two or more of the $|d_i|$ are equal, assign each tied value the mean of the rank positions the tied values occupy. If, for example, the three smallest $|d_i|$ are all equal, place them in rank positions 1, 2, and 3, but assign each a rank of $(1 + 2 + 3)/3 = 2$.

Table 6 Confidence intervals (CI) and hypothesis test for the single population mean μ , for the difference between two population means μ_1 and μ_2 , for population variance σ^2 and for the ratio of the variances when sampling from normally distributed populations

Fig. 17 Critical regions for a free distribution.

3. Assign each rank the sign of the $|d_i|$ that yields that rank.
4. Find T_+ the sum of the ranks with positive signs, and, T_- , the sum of the ranks with negative signs.

The Wilcoxon test statistic is either T_+ or T_- , depending on the nature of the alternative hypothesis. If the null hypothesis is true, that is, if the true population mean is equal to the hypothesized mean, the probability of observing a positive difference $d_i = x_i - \mu_0$ of a given magnitude is equal to the probability of observing a negative difference of the same magnitude. Then, in repeated sampling, when the null hypothesis is true and the assumptions are met, the expected value of T_+ is equal to the expected value of T_- . However, when H_0 is true, we do not expect a large difference in their values. Consequently, a sufficiently small value of T_+ or a sufficiently small value of T_- will cause rejection of H_0 . When the alternative hypothesis is two-sided ($\mu \neq \mu_0$), either a sufficiently small value of T_+ or a sufficiently small value of T_- will cause rejection of H_0 . The test statistic, then, is T_+ or T_- , whichever is smaller. To simplify notation, we call the smaller of the two T . Similarly, when the one-sided alternative hypothesis is true a sufficiently small (or large) value of T_+ (or T_-) will cause rejection of H_0 , and T_+ (or T_-) is the test statistic. Critical values of the Wilcoxon test statistic are given in probability tables well known in literature. The following are the decision rules for the three possible alternative hypotheses:

1. $H_1: \mu \neq \mu_0$. Reject H_0 at the level of significance α if the calculated T is smaller than or equal to the tabulated T for n and preselected $\alpha/2$ (see Fig. 17).
2. $H_1: \mu < \mu_0$. Reject H_0 at the level of significance α if T_+ is less than or equal to the tabulated T for n and preselected α .
3. $H_1: \mu > \mu_0$. Reject H_0 at the level of significance α if T_- is less than or equal to the tabulated T for n and preselected α .

The Mann-Whitney test

Another important non-parametric test is the Mann-Whitney test based on the ranks of the observations (Mann and Whitney, 1947). The assumptions underlying the Mann-Whitney test are as follows: (i) the two samples, of size n and m , respectively, available for analysis have been independently and randomly drawn from their respective populations; (ii) the measurement scale is at least ordinal; (iii) the variable of interest is continuous; (iv) if the populations differ at all, they differ only with respect to their medians. When these assumptions are met we test the null hypothesis that the two populations have equal medians against either of the three possible alternatives: (1) the populations do not have equal medians (two-sided test), (2) the median of population 1 is larger than the median of population 2 (one-sided test), or (3) the median of population 1 is smaller than the median of population 2 (one-sided test). If the two populations are symmetric, so that within each population the mean and median are the same, the conclusions we reach regarding the two population medians will also apply to the two population means. In particular, the null and alternative hypotheses are given by:

$$H_0 : M_X = M_Y (\leq, \geq) \text{ vs } H_1 : M_X \neq M_Y (>, <)$$

where M_X is the median of a population of population 1 and M_Y is the median of population 2. For a fixed significance level α , we compute the test statistic combining the two samples and rank all observations from smallest to largest while keeping track of the sample to which each observation belongs. Tied observations are assigned a rank equal to the mean of the rank positions for which they are tied. The test statistic is

$$T = S - \frac{n(n+1)}{2}$$

where n is the number of sample X observations and S is the sum of the ranks assigned to the sample observations from the population of X values. The choice of which sample's values we label X is arbitrary. If the median of the X population is smaller than the median of the Y population, as specified in the alternative hypothesis, we would expect (for equal sample sizes) the sum of the ranks assigned to the observations from the X population to be smaller than the sum of the ranks assigned to the observations from the Y population. A sufficiently small value of T will cause rejection of H_0 . Critical values of the Mann-Whitney test statistic are given in probability table well known in literature. The following are the decision rules for the three possible alternative hypotheses:

1. $H_1: M_X \neq M_Y$. Reject H_0 if the computed T is either less than $w_{\alpha/2}$, or greater than $w_{1-\alpha/2}$, where $w_{\alpha/2}$ is the tabulated critical value of T for n , the number of X observations; m , the number of Y observations; and $\alpha/2$, the chosen level of significance, and $w_{1-\alpha/2} = nm - w_{\alpha/2}$. For instance, see Fig. 17.

Table 7 Clinical depression data. For each patient, the dataset contains the following characteristic or variables. Hospt: the patient's hospital with 1, 2, 3, 5, or 6; Treat: the treatment received by the patient (Lithium, Imipramine, or Placebo); Outcome: recurrence or no recurrence occurred during the patient's treatment; Time: the length (in days) of the patient's participation in the study in terms of recurrence or no recurrence; AcuteT: the time (in days) that the patient was depressed prior to the study; Age: the age of the patient in years, when the patient entered the study; Gender: The patient's gender (1 = Female, 2 = Male). The number of patients are 109

2. $H_1: M_X > M_Y$. Reject H_0 if the computed T is less than $w_{1-\alpha}$, where $w_{1-\alpha} = nm - w_\alpha$ is the tabulated critical value for n , the number of X observations; m , the number of Y observations; and α , the chosen level of significance.
3. $H_1: M_X < M_Y$. Reject H_0 if the computed T is less than w_α , where w_α is the tabulated critical value of T for n , the number of X observations; m , the number of Y observations; and α , the chosen level of significance.

When either n or m is greater than 20 we compute the following test statistic

$$z = \frac{T - nm/2}{\sqrt{nm(n+m+1)/12}} \sim N(0, 1)$$

and compare the result, for significance, with critical values of the standard normal distribution. Finally, many computer packages give the test value of both the Mann–Whitney test (U) and the Wilcoxon test (W). These two tests are algebraically equivalent tests, and are related by the following equality when there are no ties in the data:

$$U + W = \frac{m(m + 2n + 1)}{2}$$

Case Studies

In this section, we consider two datasets as case studies. The first is the Clinical depression dataset downloaded from <http://bolt.mph.ufl.edu> (for instance, see [Table 7](#)). The depression is the most common mental illness in the United States, affecting 19 million adults each year (Source: NIMH, 1999). Nearly 50% of individuals who experience a major episode will have a recurrence within 2–3 years. In a study conducted by the National Institutes of Health, 109 clinically depressed patients were separated into three groups, and each group was given one of two active drugs (imipramine or lithium) or no drug at all. For each patient, the dataset contains the following characteristic or variables:

Hospt: The patient's hospital, represented by a code for each of the 5 hospitals (1, 2, 3, 5, or 6).

Treat: The treatment received by the patient (Lithium, Imipramine, or Placebo).

Outcome: Whether or not a recurrence occurred during the patient's treatment (Recurrence or No Recurrence).

Time: Either the time (days) till recurrence, or if no recurrence, the length (days) of the patient's participation in the study.

AcuteT: The time (days) that the patient was depressed prior to the study.

Age: The age of the patient in years, when the patient entered the study.

Gender: The patient's gender (1=Female, 2=Male).

Using these data, researchers are interested in comparing therapeutic solutions that could delay or reduce the incidence of recurrence.

In the second dataset a researcher designed an experiment to assess the effects of prolonged inhalation of cadmium oxide. Fifteen laboratory animals served as experimental subjects, while 10 similar animals served as controls. The variable of interest was hemoglobin level following the experiment. The results are shown in [Table 8](#). We wish to know if we can conclude that prolonged inhalation of cadmium oxide reduces hemoglobin level.

Results

In this section, we describe the main results obtained from the descriptive and inferential analysis using the information contained [Tables 7](#) and [8](#).

The first dataset (Clinical depression dataset) is composed by four categorical variables (Hospt, Treat, Outcome, Gender) and two numerical variables (Time, Time, AcuteT). Bar plots for Hospt, Outcome, and Gender variables are plotted for a qualitative analysis of these data (see [Fig. 18](#)). On the contrary, a quantitative descriptive analysis is performed for the variable age of patients. [Table 9](#) summarizes the main results of some statistical measures computed using the formulas shown in [Table 3](#). Finally, the confidence intervals (CI) and hypothesis test for the difference between two population means μ_1 and μ_2

Fig. 18 Bar plots of the qualitative variables: Host (A), Outcome (B) and Gender (B). The first plot indicates that the number of patients from hospital 5 is greater than the others. The second plot shows that the outcome of the treatment for patients with no recurrence exceeds that with recurrence. The third plot displays that the number of female patients is greater than that of males.

Total	109	1	100			4,397	197,765	
Mean	Median	Mode	Variance	Standard deviation	First quartile	Third quartile	IQR	
40.34	38.8	28	187.04	13.68	28.16	51.14	22.98	

are detected using the second listed test statistic illustrated in Table 6. In particular, we test the effect of the treatment (Imipramine) with respect to the control group (Placebo) during the participation of patients in the study (Time). The sample mean estimates are 37.58 and 63.06 for each group under investigated ($n=34$ -Imipramine and $m=38$ -Placebo). The test statistic (two-tailed test) is $t = -2.38$ with 70 degree of freedom, the confidence interval at level $\alpha=0.05$ is $(-46.84, -4.12)$ and the p -value is significant ($p\text{-value}=0.0201 < 0.05$). Hence, the null hypothesis H_0 is rejected which means that the true difference in means is not equal to zero. This means that there is an evidence on the effects of therapy in the treatment of patients with Imipramine during the study.

In the second dataset, we consider the hemoglobin levels (measured in grams) for 25 laboratory animals, divided in two groups: exposed (X) and not exposed (Y) to cadmium oxide. We assume that the assumptions of the Mann-Whitney test are applicable. Therefore, with $n=15$, $m=10$ and $\alpha=0.05$, we find the statistic test (two-tailed test) $T=25$ and the p -value equal to 0.006008 ($p\text{-value} < 0.05$, statistically significant). We conclude that M_X is smaller than M_Y . This leads to the conclusion that prolonged inhalation of cadmium oxide does reduce the hemoglobin level.

Software

We use the R statistical software (see Relevant Websites section) to plot the graphs and to perform the descriptive statistics and statistical inference. In particular, we apply the common used statistical packages in R.

Conclusions

Biostatistics can be defined as the application of mathematics used in statistics to the fields of biological sciences and medicine. When research activities involve data collection on a sample of a population, an understanding of descriptive and inferential analysis become essential for an accurate study of the phenomenon to draw conclusions and make inferences about the entire population. The two major areas of statistics are the descriptive statistics and the inferential statistics. The aim of the first areas is to collect data and obtain a synthesis of this information in order to give a descriptive overview of the data. On the other hand, the goal of the statistical inference is to decide whether the findings of an investigation reflect chance or real effects at a given level of probability. Both estimation and testing hypothesis are covered. These statistical tools are useful for researchers in order to decide what type of study to use for their research project, how to execute the study on patients and well people, and how to evaluate the final results.

Descriptive Statistics

Introduction

Statistics is a mathematical science for collecting, analyzing, interpreting and drawing conclusions from a set of data. The first instance of descriptive statistics was given by the “bills of mortality” collected by John Graunt’s in 1662. Around 1749, the meaning of statistics was limited to information about “states” to design the systematic collection of demographic and economic data. In the early 19th century, accumulation of information intensified, and the definition of statistics extended to include disciplines concerned with the biology and the biomedicine. The main important areas of statistics are the descriptive statistics and the inferential statistics. The first statistical method gives numerical and graphic procedures to summarise a collection of data in a clear and understandable way without assuming any underlying structure for such data, the second one provides procedures to draw inferences about a population on the basis of observations obtained from samples. Therefore, the use of descriptive and inferential methods enables researchers to summarize findings and conduct hypothesis testing. The descriptive statistics is the primary step in any applied scientific investigation to simplify large amounts of data in a sensible way. Indeed, the goal of descriptive statistics is to give a clear explanation and interpretation of the information collected during an experiment. For instance, in medicine and biology, the observations obtained by a phenomenon are large in number, dispersed, variable and heterogeneous preventing the researcher from directly understanding it. To have a full knowledge of the under investigated phenomenon, it is first necessary to arrange, describe, summarize and visualize the collected data (Spriestersbach *et al.*, 2009).

In this article, we present two statistical descriptive methods: graphical and numerical. The graphs and tables are used to organize and visualize the collected data. Numerical values are computed to summarize the data. Such numbers are called parameters if they describe population; they are called statistics if they describe a sample. The most useful numerical value or statistics for describing a set of observations are the measures of location, dispersion and symmetry. Generally, graphical methods are better suited than numerical methods for identifying patterns in the data, although the numerical approaches are more precise and objective. Since the numerical and graphical approaches complement each other, it is wise to use both. In the following sections, we first introduce the statistical data types (quantitative or qualitative), and then, the way to organize and visualize collected data using tables and graphs. Several kinds of statistics measures (location, dispersion and symmetry) are also discussed to provide a numerical summary of data (Manikandan, 2011a,b,c; Wilcox and Keselman, 2003). Finally, clinical data are elaborated and discussed as an illustrative example.

Statistical Data Types

The goal of descriptive statistics is to gain understanding from data. Population and sample are two basic concepts of statistics. Population can be defined as the set of individuals or objects in a statistical study. While, a sample is a subset of the population from which information is collected. In other words, a statistical population is the set of measurements corresponding to the entire collection of units for which inferences are to be performed, a statistical sample is the set of measurements that are collected in the course of an investigation from the statistical population. Each measurement is defined as statistical unit. This denomination inherited from demography that was the first application field of statistics. A statistical variable is each aspect or characteristic of the statistical unit and it varies from one individual member of the population to another. A statistical variable can be qualitative or quantitative, depending on whether their nature is countable or not. Examples of variables for humans are height, weight, sex, status, and eye color. The first two variables are quantitative variables, the last three are qualitative variables. Quantitative variables can be classified as either discrete or continuous, while qualitative variables can be divided into categorical and ordinal. We define a discrete variable as a finite or countable number of values, while, a continuous variable as a measurement that can take any value in an interval of the real line.

Organization and Visualization of Data

We define each individual or object of data as observation. The collection of all observations for particular variables is called data set or data matrix. Data set is composed by the values of variables recorded for a set of sampling units. Note that in the case of qualitative variable, we assign numbers to the different categories, and thus transform the categorical data to numerical data in a trivial sense. For example, cancer grade can be coded using the values 1, 2 and 3 depending on the amount of abnormality (see Table 1).

Frequency Distribution

Let N be the number of individuals in the population and let X be a variable assuming the values x_i , $i = 1, 2, \dots, k$. We denote with n_i the number of times the value x_i appears in the data set. This value is called absolute frequency of the observed value

Table 1 Tumor data table, with different classification grades

Unit	Gender	Age	Tumor	Grade	Year first diagnosis
1	M	34	Prostate cancer	II	2000
2	M	45	Brain cancer	II	2003
3	F	50	Breast cancer	III	2005
...	...	...	...	...	...
90	F	62	Ovarian cancer	I	2001

Table 2 Frequency distribution

Statistical units i	Values of characteristics x_i	Absolute frequency n_i	Relative frequency f_i	Cumulative absolute frequency N_i	Cumulative relative frequency F_i
1	x_1	n_1	$f_1 = \frac{n_1}{N}$	$n_1 = N_1$	$f_1 = F_1$
2	x_2	n_2	$f_2 = \frac{n_2}{N}$	$n_1 + n_2 = N_2$	$f_1 + f_2 = F_2$
...	...	...	...	...	...
i	x_i	n_i	$f_i = \frac{n_i}{N}$	$n_1 + n_2 + \dots + n_i = N_i$	$f_1 + f_2 + \dots + f_i = F_i$
...	...	...	...	...	...
k	x_k	n_k	$f_k = \frac{n_k}{N}$	$n_1 + n_2 + \dots + n_k = N$	$f_1 + f_2 + \dots + f_k = 1$
Total		N	1		

Table 3 Frequency distribution of tumor grades for 60 patients

Tumor	n_i	f_i
I	36	0,6
II	9	0,15
III	15	0,25
Total	60	1,00

with x_i , and the ratio

$$f_i = \frac{n_i}{N} \quad (1)$$

indicates the relative frequency of the observed value with n_i . In other words, f_i is the proportion on the total population N of individuals presenting the value with x_i . In particular, Eq. (1) satisfies the following conditions:

$$\sum_{i=1}^k n_i = N, \quad \sum_{i=1}^k f_i = 1$$

The observed values of each variable, their absolute and relative frequencies are usually organized in a table called frequency distribution (see Table 2). Sometimes, we are often interested in the percentage frequency that is obtained by dividing the relative frequency by the total number of observations N and multiplying the result by 100. The sum of absolute (or relative) frequencies of all the values equal to or less than the considered value is called cumulative absolute (or relative) frequency. This is represented as N_i (or F_i). If cumulative frequencies are represented in a table then it is called as cumulative frequency distribution (see Table 2). The frequency distribution is useful when data sets are large and the number of different values is not too large. For example, if we consider the brain tumor stage in a sample of 60 patients, then we can use the frequency distribution to compute the absolute and relative frequency (see Table 3).

Qualitative variable

The number of observations that fall into a particular class (or category) of a qualitative variable indicates the frequency (or count) of the class. In this case, cumulative frequencies make sense only for ordinal variables, not for nominal variables. The qualitative data can be represented graphically either as a pie chart or as a horizontal or vertical bar graph. A pie chart is a disk divided into pie-shaped pieces proportional to the relative frequencies of the classes. To obtain angle for any class, we multiply the relative frequencies by 360° , which corresponds to the complete circle. A horizontal bar graph displays the classes on the horizontal axis and the absolute frequencies (or relative frequencies) of the classes on the vertical axis. The absolute frequency (or relative frequency) of each class is represented by vertical bar whose height is equal to the absolute frequency (or relative frequency) of the

Table 4 Frequency distribution based on class intervals. The symbol -| means that only the superior limit is included into the class interval

Class intervals $x_i - x_{i+1}$	Absolute frequency n_i	Relative frequency f_i	Cumulative absolute frequency N_i	Cumulative relative frequency F_i
$x_1 - x_2$	n_1	$f_1 = \frac{n_1}{N}$	$n_1 = N_1$	$f_1 = F_1$
$x_2 - x_3$	n_2	$f_2 = \frac{n_2}{N}$	$n_1 + n_2 = N_2$	$f_1 + f_2 = F_2$
...	...	...	...	...
$x_{i-1} - x_i$	n_i	$f_i = \frac{n_i}{N}$	$n_1 + n_2 + \dots + n_i = N_i$	$f_1 + f_2 + \dots + f_i = F_i$
...	...	...	...	...
$x_{k-1} - x_k$	n_k	$f_k = \frac{n_k}{N}$	$n_1 + n_2 + \dots + n_k = N$	$f_1 + f_2 + \dots + f_k = 1$
Total	N	1		

class. In a bar plot, its bars do not touch each other. In a vertical bar graph, the classes are displayed on the vertical axis and the frequencies (absolute and relative) of the classes on the horizontal axis. Nominal data is best displayed by pie chart and ordinal data by horizontal or vertical bar graph.

Quantitative variable

Quantitative variable can also presented by a frequency distribution. The data of a discrete variable can be summarised in a frequency distribution as in [Table 2](#). Differently, continuous data are first grouped into classes (or categories) and, then collected into a frequency distribution (see [Table 4](#)). The main steps in a process of grouping quantitative variable into classes are:

1. Find the minimum x_{min} and the maximum x_{max} values into the data set.
2. Construct intervals of equal length that cover the range between x_{min} and x_{max} without overlapping. These intervals are called class intervals, and their end points are defined class limits. The magnitude of class interval depends on the range and the number of classes. The range is the difference between x_{max} and x_{min} . A class interval is generally in multiples of 5, 10, 15 and 20. The magnitude of class is given by

$$d = \frac{x_{max} - x_{min}}{K}$$

where K is the number of classes equal to $K = 1 + 3.322 \log_{10}(k)$.

3. Count the number of observations in the data that belongs to each class interval. The count in each class is the absolute class frequency.
4. Calculate the relative frequencies of each class by dividing the absolute class frequency by the total number of observations into the data.

In this case, the information contained in [Table 4](#) can be illustrated graphically using histograms (or vertical bar graph) and cumulative frequency curves. A histogram is a graphical representation of the absolute or relative frequencies for each value of the variables. It is like a horizontal bar graph where the bars are closed each other. In particular, a histogram is composed by rectangles over each class where the area of each rectangle is proportional to its frequency. The base of rectangles are the range of each class, i.e. the difference between x_{i+1} and x_i , for $i = 1, \dots, k$, while the height of the rectangle, called class intensity, is given by

$$h_i = \frac{n_i}{x_{i+1} - x_i}, i = 1, \dots, k$$

A cumulative frequency curve is a plot of the number or percentage of individuals falling in or below each value of the characteristic. If quantitative data is discrete, then the variable should graphically be presented by a bar graph. Also in the case in which the frequency table for quantitative variable is composed by unequal class intervals, the variable can be represented by a bar graph.

Statistical Measures

In this section we present three types of statistical measures that describe and summarise the observed data: the measures of central tendency, the measures of dispersion, and the measures of symmetry. They are called statistics, i.e., functions or modifications of the obtained data. These descriptive measures are a direct consequence of the frequency distribution of the data. In fact, they provide a numerical summary of the frequency distribution.

Measures of Central Tendency

The central tendency of a frequency distribution is a statistical measure that identifies a single value as representative of an entire distribution ([Manikandan, 2011a](#)). It aims to provide an accurate description of the data and it is a numerical value that is most representative of the collected data. The mean, median, quartiles and mode are the commonly used measures of central tendency. The mean is the most used measure of central tendency. The (arithmetic) mean is the sum of all the values $x_1, x_2, \dots, x_k$ in the data

set divided by the number of observations k ($k \leq N$). Denoting the sample mean by $\bar{x}$, it is given by the formula

$$\bar{x} = \frac{1}{k} \sum_{i=1}^k x_i \quad (2)$$

Sometimes the prefix “sample” is dropped, but it is used to avoid the confusion of $\bar{x}$ with the population mean μ on the entire population. In this case, the mean is computed by adding all the values in the data set divided by the number of observations N . The formula is

$$\mu = \frac{1}{N} \sum_{i=1}^N x_i \quad (3)$$

In terms of frequency distribution, the sample mean is given by

$$\bar{x} = \frac{1}{k} \sum_{i=1}^k x_i n_i \quad (4)$$

where n_i is the absolute frequency. In the case of class frequency distribution, we first calculate the central value $c_i = \frac{x_{i+1} + x_i}{2}$ and, then, the sample mean $\bar{x}$ with the following formulas

$$\bar{x} = \frac{1}{k} \sum_{i=1}^k c_i n_i \quad (5)$$

The median is a measure of location that separates the set of values in half, so that the data in one half are less than or equal to the median value and the data in the other half are greater or equal to the median value (Manikandan, 2011b). It divides the frequency distribution exactly into two halves. Fifty percent of observations in a distribution have scores at or below the median. Hence, median is the 50th percentile. To compute the median, we first collect the data in increasing order and then determine the middle value in the ordered list. In particular, we can distinguish two cases:

1. If the number of observations is odd, then the median is the value that occupies the middle position into the data. If we let k denote the number of observations, then the sample median is at position $\frac{k+1}{2}$ into the ordered list of data.
2. If the number of observations is even, then the median is the mean of the two middle observations into the ordered data, i.e., the mean of the values at position $\frac{k}{2}$ and $\frac{k}{2} + 1$ into the ordered data.

In the case of (discrete) frequency distribution, we first compute the value $\frac{k}{2}$ and, then we consider the absolute cumulative frequency that is greater than $\frac{k}{2}$, i.e. $N_i \geq \frac{k}{2}$, for $i = 1, 2, \dots, k$. The corresponding value x_i is the median. In terms of grouped value, we first identify the median class as the class that includes the 50% of cumulative relative frequencies, i.e., $F_i \geq 0.50$, for $i = 1, 2, \dots, k$. Then, under the assumption that the frequencies are uniformly distributed, we compute the median M_e as the following approximation

$$M_e \approx x_i + (x_{i+1} - x_i) \frac{0.5 - F_{i-1}}{F_i - F_{i-1}} \quad (6)$$

The quartiles (or percentiles) are location measures that divide the data set into four equal parts, each quartile contains the 25% of the total observations. The first quartile Q_1 (lower quartile) is the number below which lies the 25% of the bottom data. Q_1 is at position $\frac{k+1}{4}$ into the ordered sample data. The second quartile Q_2 is the median of the data. The data are divided into two equal parts, the bottom 50% and the top 50% and it is at position $\frac{k+1}{2}$ into the ordered sample data. The third quartile Q_3 (upper quartile) is the number above which lies the 75% of the top data. Q_3 is at position $\frac{3(k+1)}{4}$ into the ordered sample data. In the case of class frequency, the first quartile class Q_1 is the class that includes the 25% of cumulative relative frequencies, i.e. $F_i \geq 0.25$, for $i = 1, 2, \dots, k$, while the third quartile class Q_3 is the class that includes the 75% of cumulative relative frequencies, i.e., $F_i \geq 0.75$, for $i = 1, 2, \dots, k$. Under the assumption that the frequencies are uniformly distributed, the first quartile class Q_1 and the third quartile class Q_3 are approximately equal to

$$Q_1 \approx x_i + (x_{i+1} - x_i) \frac{0.25 - F_{i-1}}{F_i - F_{i-1}}, Q_3 \approx x_i + (x_{i+1} - x_i) \frac{0.75 - F_{i-1}}{F_i - F_{i-1}} \quad (7)$$

Generally, a frequency distribution can be represented constructing a graph called boxplot (or whisker diagram) which is a standardized way of displaying the data distribution based on five number summary: x_{min} , Q_1 , $Q_2 = M_e$, Q_3 , x_{max} . The central rectangle spans the first quartile to the third quartile (the interquartile range). The segment inside the rectangle shows the median and “whiskers” above and below the box show the positions of the minimum and maximum (see Fig. 1).

The mode (or modal value) of a variable is the value that occurs most frequently in the data (Manikandan, 2011b). It is given by

$$M_o = \{x_i : n_i = \max\}, i = 1, 2, \dots, k \quad (8)$$

The mode may not exist, and even if it does, it may not be unique. This happens when the data set has two or more values of equal frequency that is greater than the other values. The mode is usually used to describe a bimodal distribution. In a bimodal distribution, the taller peak is called the major mode and the shorter one is the minor mode. For continuous data, the mode is the midpoint of the interval with the highest rectangle in the histogram. If the data are grouped into class intervals, than the mode is defined in terms of

Fig. 1 Boxplot or box and whisker diagram.

class frequencies. With grouped quantitative variable, the mode class is the class interval with highest frequency and it is given by

$$m_c = \{x_i - |x_{i+1} : h_i = \max\} \quad (9)$$

where $h_i = \frac{n_i}{x_{i+1} - x_i}$ is the class intensity. Under the assumption that the frequencies are uniformly distributed, the mode is approximately equal to

$$M_o \approx \frac{x_i + x_{i+1}}{2} \quad (10)$$

We observe that median and mode are not influenced by extreme values or outliers. On the contrary, the mean suffers of them. An outlier is an observation that lies an abnormal distance from other values in a sample from a population. It is a value that exceeds the third quartile by a magnitude greater than $1.5 \times (Q_3 - Q_1)$ or is less than the first quartile by a magnitude greater than $1.5 \times (Q_3 - Q_1)$. In addition, for qualitative and categorical data, the mode can be calculated, while the mean and median do not. On the other hand, if the data is quantitative one, we can use any one of the three averages presented. For symmetric data the mean, the median and the mode can be approximately equal; for skew (or asymmetric) data the median is less sensitive than the mean to extreme observations (outliers). As the mean, the mode and the median have the corresponding population median and population mode, which are all unknown. In fact, the sample mean, the sample median, and the sample mode can be used to estimate the values of these corresponding unknown population values.

Measures of Dispersion

The measures of central tendency are representatives of a frequency distribution but they are not sufficient to give a complete representation of a frequency distribution (Manikandan, 2011c). Two data sets can have the same mean but they can be entirely different. Thus, to describe data, one needs to know also the extent of variability. This is given by the measures of dispersion. A measure of dispersion (called also variability, scatter, or spread) is a statistics that indicates the degree of variability of data. Range, interquartile range, variance, standard deviation and coefficient of variation are the commonly used measures of dispersion. The (sample) range is obtained by computing the difference between the largest observed value $x_{\max}$ of the variable in a data set and the smallest one $x_{\min}$. This measures is easy to compute even if a great deal of information is ignored. In fact, only the largest and smallest values of the variable are considered while the other observed values are disregarded. In addition, the range is always increase, when additional observations are included into the data set which means that the range is overly sensitive to the sample size. The (sample) interquartile range (IQR) is equal to the difference between 75th and 25th percentiles, i.e. the upper and lower quartiles

$$\text{IQR} = Q_3 - Q_1 \quad (11)$$

The (sample) interquartile range represents the length of the interval covered by the center half of the observed values of the data. This measure is not distorted if a small fraction of the observed values are very large or very small.

The variance and the standard deviation are two very popular measures of dispersion. They measure the spread of data across the mean. The population variance σ^2 is the mean of the square of all deviations from the mean. Mathematically it is given as:

$$\sigma^2 = \frac{1}{N} \sum_{i=1}^N (x_i - \mu)^2 \quad (12)$$

where x_i is the value of the i th observation, μ is the population mean and N is the population size. The population standard deviation σ is defined as $\sigma = \sqrt{\sigma^2}$. In terms of frequency distribution, the (sample) variance s^2 is given by

$$s^2 = \frac{1}{k-1} \sum_{i=1}^k (x_i - \bar{x})^2 n_i \quad (13)$$

where x_i is the value of the i th observation, $\bar{x}$ is the sample mean and k is the sample size. In the last formula, the sum of the squared deviations from the mean provides a measure of total deviation from the mean of the data. If k is large the difference between the formulas (12) and (13) is minimal; if k is small, the difference is very sensitive. Generally, for calculations an easier formula is used. The equation of this formula is given by

$$s^2 = \frac{1}{k} \sum_{i=1}^k x_i^2 n_i - \bar{x}^2 \quad (14)$$

where $\bar{x}_2 = \frac{1}{k} \sum_{i=1}^k x_i^2 n_i$ is called second order statistics. This computational formula avoids the rounding errors during calculation. The (sample) standard deviation SD is given by $s = \sqrt{s^2}$. The more variation there is into the data, the larger is the standard deviation. However, the standard deviation does have its drawbacks. For instance, its values can be strongly affected by a few extreme observations. We observe that factor $k-1$ is present in both formulas (13) and (14) instead of k in the denominator, this produces a more accurate estimate of standard deviation.

In the case of class frequency distribution, we first calculate the central value c_i and, then the (sample) variance s^2 given by

$$s^2 = \frac{1}{k-1} \sum_{i=1}^k (c_i - \bar{x})^2 n_i \left(\text{or } s^2 = \frac{1}{k} \sum_{i=1}^k c_i^2 n_i - \bar{x}^2 \right) \quad (15)$$

When the two distributions are expressed in the same units and their means are equal or nearly equal, the variability of data can be compared directly by using the relative standard deviations. However, if the means are widely different or if they are expressed in different units of measurement, we cannot use the standard deviations as such for comparing the variability of both data. Therefore, we use as measure of dispersion the coefficient of variation (CV) that is the ratio of the standard deviation to the mean. The population CV is given by

$$CV = \frac{s}{|\bar{x}|} \quad (16)$$

Formula (16) for population is the ratio of the population standard deviation σ and the population mean μ . The CV is a unit-free measure and it is always expressed as percentage. The CV is small if the variation is small and it is unreliable if the mean is near zero. Hence, if we consider two groups, the one with less CV is said to be more consistent.

Measures of Symmetry

An important aspect of the data is the shape of its frequency distribution. Generally, we are interested to observe if the frequency distribution can be approximated by the normal distribution ($\mu = M_e$). The normal distribution is a continuous random variable and its density curve is symmetric, bell-shaped curve and characterised by its mean μ and standard deviation σ (Fig. 2).

Fig. 2 Normal distribution with mean=5 and standard deviation=2.5.

Fig. 3 Standard normal distribution with mean=0 and standard deviation=1.

Fig. 4 Positively skewed distribution (to the right).

A continuous random variable follows a standard normal distribution if the variable is normally distributed with mean $\mu=0$ and standard deviation $\sigma=1$ (see Fig. 3). Two important measures of shape are skewness and kurtosis. The first measure is the deviation of the distribution from symmetry (departure from horizontal symmetry), the second one measures the peakedness of the distribution (how tall and sharp the central peak is, relative to a standard bell curve). In particular, if the skewness is different from zero, then that distribution is asymmetrical, while normal distributions are perfectly symmetrical. If the kurtosis is not equal to zero, then the distribution is either flatter or more peaked than normal. We define the moment coefficient of skewness of a sample as

$$\gamma_1 = \frac{\frac{1}{k} \sum_{i=1}^k (x_i - \bar{x})^3}{\left(\frac{1}{k} \sum_{i=1}^k (x_i - \bar{x})^2 \right)^{3/2}} \quad (17)$$

where $\bar{x}$ is the mean and k is the sample size, as usual. The numerator is called the third moment of the variable x . The skewness can also be computed as the average value of z^3 , where z is the familiar z-score, i.e. $z = \frac{x - \bar{x}}{\sigma}$. In terms of frequency distribution, the

skewness is

$$\gamma_1 = \frac{\sqrt{k}}{(k-1)\sqrt{k-1}s^3} \sum_{i=1}^k (x_i - \bar{x})^3 n_i \quad (18)$$

where s is the sample standard deviation and k the sample size. Similarly, for class frequency distribution, the skewness is

$$\gamma_1 = \frac{\sqrt{k}}{(k-1)\sqrt{k-1}s^3} \sum_{i=1}^k (c_i - \bar{x})^3 n_i \quad (19)$$

Fig. 5 Negatively skewed distribution (to the left).

Fig. 6 Kurtosis distributions: a distribution with kurtosis equal to zero is called mesokurtic or mesokurtotic (line red); a distribution with positive kurtosis is called leptokurtic, or leptokurtotic (line blue); a distribution with negative kurtosis is called platykurtic, or platykurtotic (line gold).

Negative values of γ_1 indicate that the data are skewed left, positive values of γ_1 show that the data are skewed right. By skewed left, we mean that the left tail is long relative to the right tail (see Fig. 4). Similarly, skewed right means that the right tail is long relative to the left tail (see Fig. 5). If the data are multi-modal, then this may affect the sign of the skewness. An alternative formula is the Galton skewness (also known as Bowley's skewness)

$$\gamma_1 = \frac{Q_1 + Q_3 - 2Q_2}{Q_3 - Q_1} \quad (20)$$

where Q_1 is the lower quartile, Q_3 is the upper quartile, and Q_2 is the median.

Table 5 Simulated data. The dataset contains the following variables: Age, Sex (M= male, F= female), Alcohol (1= yes, 0= no), Smoke (1= yes, 0= no) and Nationality (Italian and Asiatic) of 50 patients

	<i>Age</i>	<i>Sex</i>	<i>Alcohol 1= yes, 0= no</i>	<i>Smoke 1= yes, 0= no</i>	<i>Nationality</i>
Patient 1	50	M	1	0	Italian
Patient 2	55	F	0	1	Italian
Patient 3	25	F	0	1	Asiatic
Patient 4	30	M	1	1	Asiatic
Patient 5	37	M	0	1	Asiatic
Patient 6	52	M	0	1	Italian
Patient 7	42	M	0	1	Italian
Patient 8	60	F	1	0	Asiatic
Patient 9	41	F	1	0	Asiatic
Patient 10	38	F	1	0	Asiatic
Patient 11	62	M	0	0	Asiatic
Patient 12	65	M	0	0	Asiatic
Patient 13	32	M	0	0	Asiatic
Patient 14	33	M	0	1	Italian
Patient 15	50	M	0	1	Italian
Patient 16	44	M	1	1	Italian
Patient 17	45	M	0	0	Italian
Patient 18	50	M	0	1	Asiatic
Patient 19	60	M	0	1	Asiatic
Patient 20	37	M	1	0	Asiatic
Patient 21	56	F	0	0	Italian
Patient 22	57	F	0	0	Italian
Patient 23	48	M	0	1	Asiatic
Patient 24	50	F	1	1	Asiatic
Patient 25	27	M	0	1	Asiatic
Patient 26	43	F	1	0	Italian
Patient 27	53	F	0	0	Italian
Patient 28	30	M	0	0	Asiatic
Patient 29	25	F	0	0	Italian
Patient 30	28	M	1	1	Asiatic
Patient 31	50	M	1	1	Asiatic
Patient 32	69	F	1	1	Asiatic
Patient 33	50	M	1	1	Italian
Patient 34	50	M	1	1	Italian
Patient 35	50	M	1	0	Italian
Patient 36	50	M	1	0	Italian
Patient 37	50	M	0	0	Asiatic
Patient 38	50	F	0	1	Asiatic
Patient 39	50	F	0	1	Italian
Patient 40	39	F	0	1	Italian
Patient 41	50	M	0	1	Italian
Patient 42	46	F	0	1	Italian
Patient 43	50	F	0	1	Asiatic
Patient 44	50	F	0	0	Asiatic
Patient 45	50	M	0	0	Asiatic
Patient 46	67	M	0	0	Italian
Patient 47	70	M	1	0	Asiatic
Patient 48	61	M	0	0	Italian
Patient 49	68	F	1	1	Italian
Patient 50	45	M	0	1	Asiatic

The kurtosis can be explained in terms of the central peak. Higher values indicate a higher, sharper peak; lower values indicate a lower, less distinct peak. As skewness involves the third moment of the distribution, kurtosis involves the fourth moment and it is defined as

$$\gamma_2 = \frac{\frac{1}{k} \sum_{i=1}^k (x_i - \bar{x})^4}{\left(\frac{1}{k} \sum_{i=1}^k (x_i - \bar{x})^2 \right)^2} \quad (21)$$

Similarly, in terms of frequency distribution, the kurtosis is

$$\gamma_2 = \frac{k(k+1)}{(k-1)(k-2)(k-3)s^4} \sum_{i=1}^k (x_i - \bar{x})^4 n_i \quad (22)$$

$$\gamma_2 = \frac{k(k+1)}{(k-1)(k-2)(k-3)s^4} \sum_{i=1}^k (c_i - \bar{x})^4 n_i \quad (23)$$

Usually, kurtosis is quoted in the form of excess kurtosis (kurtosis relative to normal distribution kurtosis). Excess kurtosis is simply kurtosis less 3. In fact, kurtosis for a standard normal distribution is equal to three. There are three different ways to define the kurtosis. A distribution with excess kurtosis equal to zero (and kurtosis exactly 3) is called mesokurtic, or mesokurtotic. A distribution with positive excess kurtosis (and $\gamma_2 > 3$) is called leptokurtic, or leptokurtotic. A distribution with negative excess kurtosis (and $\gamma_2 < 3$) is called platykurtic, or platykurtotic. For instance, see Fig. 6. In terms of shape, a leptokurtic distribution has fatter tails while a platykurtic distribution has thinner tails. Finally, if you have the whole population, then γ_1 and γ_2 are the measure of skewness, formula (17), and kurtosis, formula (21).

Data Analysis and Results

In this section, we describe an illustrative example and the results obtained by using the main descriptive tools and measures. We simulate a clinical random dataset composed by 50 patients and different type of variables (quantitative and qualitative). More precisely, the data matrix, in Table 5, shows information about age, sex (M-male; F-female), alcohol (1=yes, 0=no), smoke (1=yes, 0=no) and nationality (Italian, Asiatic) for each patient. Hence, the dataset is composed by four categorical variables (sex, alcohol, smoke, and nationality) and one numerical variable (age). In the first step of our analysis, we plot each variable in order to examine the relative distribution. In particular, we use the pie chart for the qualitative variables alcohol and smoke (see Fig. 7). In the graph A, we observe that the percentage of patients who alcoholic drinks is 36%, while it is 64% for patients do not consume alcoholic drinks. In the graph B, we notice that the percentage of patients who smoke is 54%, while it is 46% for patients do not smoke. Fig. 8 shows the vertical bar plot of the patient's frequencies grouped by nationality, while Fig. 9 displays the horizontal bar plot of the patient's frequencies grouped by gender. The first plot indicates that the community of Asiatic people is greater than of Italian one, while the second graph shows that the males are more numerous than females. In the second step of the analysis, we analyze the quantitative variable: age. We organize the relative data in class frequency. In particular, we first divide the variable age in 7 classes according to the procedure illustrated in Section Quantitative Variable, then, we compute the relative absolute frequencies. Based on this information, formula (1) is applied to calculate the relative frequencies and percentages for each class. The cumulative relative frequency is also computed. Therefore, the table frequency distribution, Table 6, is created. Using the data of this table, the histogram and the cumulative frequency curve of patients grouped by age are plotted (see Figs. 10 and 11).

Fig. 7 Pie chart A shows the percentage of *alcohol/no alcohol* patients; pie chart B shows *smoke/no smoke* patients.

Fig. 8 Vertical bar shows the frequency of patients grouped by nationality.

Fig. 9 Horizontal bar shows the frequency of patients grouped by gender.

In addition, the density plot of the variable age grouped in class is shown in [Fig. 12](#). We note that the density shows a bimodal distribution with two different modes that are two different peaks (local maxima). Finally, to conclude our descriptive analysis the most important statistical measures are determined. By considering the information collected in [Table 6](#), we construct the [Table 7](#). In particular, using formula (5), the mean is equal to 47.19, which means that the center of the age distribution is around 47.19 years. The median class of the variable age is the interval $(46,53]$ corresponding to $F_i \geq 0.50$, for $i=1, \dots, 7$. Hence, the median, in according to formula (6), is approximately to 48.21. Using formula (10), the first quartile Q_1 is approximately equal to 39.5 ($F_i \geq 0.25$, for $i=1, \dots, 7$), while the third quartile Q_3 is approximately equal to 52.3 ($F_i \geq 0.75$, for $i=1, \dots, 7$). The mode class is $(46,53]$. Hence, by using formula (9), the mode is approximately equal to 49.5. Median class and mode class coincide.

Finally, we calculate the measure of dispersion for variable age. Using data collected in [Table 7](#), we first compute the range, which is equal to 45. A larger range value indicates a greater spread of the data. Then, by considering formula (11), we calculate the interquartile range IQR, which is equal to 12.8. In addition, the variance and the standard deviation are equal to 132.88 and 11.52, respectively. While the coefficient of variation CV is 0.24. This means that exists a low variability among the data, hence the existing patterns can be seen clearly. To obtain these last results we use formula (15) and (16).

Table 6 Class Frequency Distribution of patients grouped by age. The absolute, relative and cumulative relative frequency are computed

Class intervals	n_i	f_i	$f_i(\%)$	F_i
24 -I 32	7	0.14	14	0.14
32 -I 39	5	0.10	10	0.24
39 -I 46	7	0.14	14	0.38
46 -I 53	19	0.38	38	0.76
53 -I 60	5	0.10	10	0.86
60 -I 67	4	0.08	8	0.94
67 -I 74	3	0.06	6	1
Total	50	1	100	

Fig. 10 Histogram shows the absolute frequency of patients grouped for classes of age.

Fig. 11 Cumulative histogram shows the cumulative frequency of patients grouped for classes of age.

Software

We use the R statistical software (see Section Relevant Website) to plot the graphs and to compute the descriptive statistics. In particular, we apply the common used statistical packages in R.

Fig. 12 Density plot of patients grouped by age.

Table 7 Data synthesis of patients grouped by age. The interval (46,53) is the median class. This interval coincides with the mode class

Class intervals	n_i	f_i	$f_i(\%)$	F_i	c_i	c_i/n_i	c_i^2/n_i
24 - 32	7	0.14	14	0.14	28	196	5,488
32 - 39	5	0.10	10	0.24	35.5	177.5	6,301.25
39 - 46	7	0.14	14	0.38	42.5	297.5	12,643.75
46 - 53	19	0.38	38	0.76	49.5	940.5	46,554.75
53 - 60	5	0.10	10	0.86	56.5	282.5	15,961.25
60 - 67	4	0.08	8	0.94	63.5	254	16,129
67 - 74	3	0.06	6	1	70.5	211.5	14,910.75
Total	50	1	100			2359.5	117,988.8

Conclusion

The description of data is the first step for the understanding of statistical evaluations. In fact, if the data are of good quality and well presented, we can draw valid and important conclusions. In this work different descriptive statistical procedures are explained. These include the organization of data, the frequency distribution and the graphical presentations of data. The concepts of central tendency, dispersion and symmetry, called summary statistics, are deeply investigated for a complete exploratory data analysis.

Measurements of Accuracy in Biostatistics

Introduction

Biostatistics is essentially the application of statistics to problems in biology and medicine. It has been playing an important role in a wide range of applications. Examples include the design of biological experiments, evaluation of the spread of a disease (Deardon *et al.*, 2014), modelling and hypothesis generation (Shmueli, 2010).

Biological data (both quantitative or qualitative) are highly variable and diverse. Range, mean deviation, standard deviation (SD), and coefficient of variation serve as measures of variability for biological samples (Bhuyan *et al.*, 2016). Range is defined as the difference between the highest and the lowest figures. Mean deviation is the average value of the deviations from the arithmetic mean of a biological sample. SD depicts the root mean square of the mean deviation. Coefficient of variation is a measure for comparing relative variability in biological sample. Some of the fundamental concepts in biostatistics as listed by Lopes *et al.* (2014), for quality measure are indicated in Fig. 1 and described below.

- Error indicates deviation of the biological results from the “true” value. Random deviations/errors are quantifiable with standard deviation and systematic deviations/errors are quantifiable with “difference of mean values”.
- Accuracy measure the closeness of obtained biological results to the “true” value.
- Precision serves as the measure of dispersion around the mean value and may be represented by standard deviation or range.
- Bias is the measure of consistent deviation of biological results from “true value” caused by systematic errors.

The biological studies often demand performance analysis by comparison of data (for example, results obtained for a case or control samples). The statistical tools to quantify such biological studies are the correlation-tests, the t-tests and regression analysis etc. The tests are dependent on probabilistic values, which represent the chance of occurrence of an event. The commonly used statistical tests are enlisted in Section “Relevant Statistical Tests for Significance of Biological Results”.

Recent advances in data generation and computer technology have a great impact on biostatistics (see “Relevant Websites section”). For example, the ability to generate data on a high-throughput scale leads to the accumulation of tremendous amounts of biological data. One major application has been in the realm of classification aiming to design a prediction model. An important contribution from biostatistics is an appreciation of the variability of the classification results and the need for good experimental design (Stuart and Barnett, 2006). Thus there is a need to understand metrics used to evaluate the performance of a predictor, which is generally assessed by the extent to which the correct class labels have been assigned. From the biological point of view, it is important not only to examine how many cases have been correctly classified in relation to a particular class, but also to indicate how well a classifier can classify an unknown case as not belonging to such a class. A standard tool used is a confusion matrix (Kohavi and Provost, 1998), from which a number of widely used metrics can be derived.

Confusion Matrix

A confusion matrix is a specific table allowing visualisation of the performance of a classification algorithm. While each row contains information associated with actual classifications, each column indicated the number of predicted classification done by a classification model.

Let TP denote the number of true positives (positive samples correctly classified as positive), FN denote the number of false negatives (positive samples incorrectly classified as negative), FP represent the number of false positives (negative samples incorrectly classified as positive), and TN represent the number of true negatives (negative samples correctly classified as negative). The confusion matrix (Kohavi and Provost, 1998) for a binary classifier is shown in Table 1. As can be seen, such a representation allows visual inspection of prediction errors with little effort as they are clearly located outside the diagonal of the table.

Fig. 1 Fundamentals for biostatistics.

Table 1 A confusion matrix for two possible outcomes positive and negative

		<i>Predicted</i>	
		<i>Positive</i>	<i>Negative</i>
Actual	Positive	TP	FN
	Negative	FP	TN

A number of widely-used statistical measures are often derived from a confusion matrix including:

- Accuracy (Ac), which is defined as the proportion of correct classifications among the total number of samples examined and can be computed using the following equation (Eq. (1)).

$$Ac = \frac{TP + TN}{TP + FP + TN + FN} \quad (1)$$

- Precision (Pr), which is defined as the ratio of true positives to all predicted positives and can be derived using Eq. (2).

$$Pr = \frac{TP}{TP + FP} \quad (2)$$

- Sensitivity (Se), which is also called True Positive Rate and Recall. It is defined as the proportion of actual positives that are correctly identified as positives which can be computed using Eq. (3). Examples include the percentage of patients that are correctly identified as having the condition.

$$Se = \frac{TP}{TP + FN} \quad (3)$$

- Specificity (Sp), which is also called True Negative Rate. It is defined as the proportion of actual negatives that are correctly identified as negatives as shown in Eq. (4). Examples include the percentage of healthy population correctly identified as healthy.

$$Sp = \frac{TN}{TN + FP} \quad (4)$$

- F-score or F measure which is defined as the harmonic mean of precision and recall (Eq. (5)). As can be seen from Eq. (5), it equally weights precision and recall and reaches the highest value of 1 when precision and recall are equal.

$$F = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \quad (5)$$

- *Receiver Operating Characteristic (ROC) curve and Area Under the ROC Curve*

A ROC space is defined by false positive rate (1 – specificity) and true positive rate (sensitivity) as x and y axes as depicted in 2. Each point in the space such as A, B, and C corresponds to an instance of a confusion matrix representing a classification result. A ROC curve is generated by connecting data points (1 – specificity, Sensitivity) obtained at different threshold levels for a given classification model.

As can be seen, the ROC space shown in Fig. 2 highlights some key properties:

1. The top left point with coordinate (0, 1) represents the perfect classification with 100% sensitivity and 100% specificity.
2. The diagonal dashed line represents prediction based on a completely random guess. Any points above the diagonal indicates a better-than-random performance while appearing in the lower right triangle suggesting the classifier performs worse than random guessing (Fawcett, 2006).
3. The ROC curve represents a tradeoff between sensitivity and specificity. Any increase in sensitivity might occur at the cost of a decrease in specificity.
4. The area under the curve (AUC) is a combined measure of sensitivity and specificity, reflecting the overall performance of a classification model. The larger the AUC value is, the better the overall performance is. While theoretically the AUC value lies between 0 and 1, the practical lower limit for the AUC is 0.5 as any classifier that has a worse-than-random performance, e.g., lies in the lower right triangle can be negated to produce a point in the upper left triangle (Park et al., 2004; Fawcett, 2006).

As an illustration, suppose a statistical classification model is to be built using gene expression data to predict the presence of a disease (positive class). In total, the model made 100 predictions, 45 of which were predicted as positives, e.g., having the disease. In reality, a total of 50 were known to have the disease, 40 of which were found in predicted positives. The resulting confusion matrix is illustrated in Table 2. The corresponding value of TP, FP, TN, and FN is 40, 5, 45, and 10 respectively. Thus, the value of Ac, Pr, Se, Sp, and F-score are 85%, 88.9%, 80%, 90%, and 0.84 respectively. The performance of the model can be represented by Point A (0.11, 080) in Fig. 2.

Fig. 2 An illustration of a ROC curve.

Table 2 An example confusion matrix for a binary classification

		Predicted	
		Positive	Negative
Actual	Positive	40	10
	Negative	5	45

Application to Multi-Class Domains

For a multi-class prediction problem with c classes, a $c \times c$ confusion matrix, $Z = (z_{ij})$, is constructed, where z_{ij} represents the number of samples predicted as members of class j while belonging in reality to class i .

Let $x_i = \sum_{1 \leq j \leq c} z_{ij}$ be the number of input samples associated with class i , and $y_j = \sum_{1 \leq i \leq c} z_{ij}$ be the number of inputs predicted to be in class j . The total number of samples is then $N = \sum_{1 \leq i, j \leq c} z_{ij} = \sum_{1 \leq i \leq c} x_i = \sum_{1 \leq j \leq c} y_j$ and the overall accuracy can be defined as: $Ac(\%) = \frac{\sum_{1 \leq i \leq c} z_{ii}}{N} \times 100$. For a class i , its individual precision, sensitivity and specificity can be written as:

$$Pr_i(\%) = \frac{z_{ii}}{y_i} \times 100 \quad (6)$$

$$Se_i(\%) = \frac{z_{ii}}{x_i} \times 100 \quad (7)$$

$$Sp_i(\%) = \frac{\sum_{\substack{k \neq i \\ j \neq i}} z_{kj}}{\sum_{\substack{k \neq i \\ 1 \leq j \leq c}} z_{kj}} \times 100 \quad (8)$$

Turning to multi-class ROC curve, things become more complex as we now need to manage c correct classification and $c^2 - c$ possible errors. One possible solution is to produce a ROC curve for each class. Thus, a total of c ROC curves are generated, each using class c_i as the positive class and the union of the remaining $(c - 1)$ classes as the negative class. While the formulation is straightforward, the solution may compromise one of key advantages exhibited by ROC curve, e.g., insensitive to class skew (Fawcett, 2006). Lane (2000) outlined key issues when extending ROC analysis to multi-class domains.

Application to Imbalanced Classification

The imbalanced classification problem is concerned with the performance of classifiers in handling highly skewed datasets in which one class significantly out represents another (He and Garcia, 2009) and is common in computational biology and bioinformatics. For example, the number of non-interacting protein pairs far outnumber interacting proteins (Jansen *et al.*, 2003). Clearly, any performance metric calculated using information from both rows in confusion matrix (actual positives and negatives) illustrated in Table 1 such as accuracy, precision and F-measure will be inherently sensitive to class distribution thus may not be suitable in the case of imbalanced classification. Utilizing two single-column-based metrics, e.g., True Positive Rate and False Positive Rate, the ROC curve assessment provides a more credible evaluation in the presence of highly skewed data (Fawcett, 2006; He and Garcia, 2009).

However, it has been suggested that when applied to biological domain, the significance of AUC values needs to be interpreted with caution as the majority of the AUC of a ROC curve may not represent biologically meaningful predictions (Scott and Barton, 2007; Browne *et al.*, 2010). Rather than measuring the AUC under the entire ROC curve, it may be more informative to consider the area under a portion of the curve referred to as the partial ROC (Collins *et al.*, 2007). For example, Browne and her colleagues developed a knowledge-driven Bayesian network (KD-BN) for the prediction of protein–protein interaction networks in which a ROC curve was constructed based on identification of TPs and FPs against specific likelihood cutoff ratios (Browne *et al.*, 2010). They compared the proposed KD-BN to a Naive Bayesian (NB)-based model using both the whole and partial ROC curves as shown in Fig. 3. No significant improvement was observed when comparing the KD-BN with NB classifiers when using the traditional ROC curve. However, as it has been estimated that only 1 in ~600 possible protein pairs interact in yeast (Jansen *et al.*, 2003), the results derived with a likelihood ratio less than 600 may not be biologically relevant and thus a large portion of the ROC curve shown in Fig. 3 may not represent biologically relevant results. This is indeed the case when examining the partial ROCs in which only the predictions made by using a selected threshold (600 for yeast based on posterior odds of an interacting protein pair) were included in the calculation of the area of the ROC. As highlighted in the inset of Fig. 3, an improvement can be observed for the KD-BN approach when the partial ROC curves are employed. This can be further confirmed with the TP/FP ratio at the corresponding likelihood ratio (Browne *et al.*, 2010). For instance, a TP/FP rate of 4.5 was obtained using the NB with the threshold set at 600. A much higher TP/FP ratio was obtained at the same threshold by the KD-BN.

Relevant Statistical Tests for Significance of Biological Results

The term “test of significance” was given by statistician Ronald Fisher (Fisher, 1929). The significance test starts with a claim to be compared. The claim tested by a statistical test is called the null hypothesis (H_0). Significance is reported as ‘p’ value

Fig. 3 Illustration of the classification performance of KD-BN and NB when inferring PPIs in yeast using both whole and partial ROC curves (inset).

(i.e., probability value). Thus p value account for differences in the sample estimates. The test of significance validates the inferences drawn from biological observations. The cutoff value for p is known as alpha, or the significance level.

- If the p-value is larger than alpha, the null hypothesis is accepted and any alternatives are rejected.
- If the p-value is smaller than alpha, the null hypothesis is rejected and any alternative is accepted.

The alpha value is typically set at 0.05 (or 5%) representing the amount of acceptable error, or the probability of rejecting a null hypothesis. The Handbook of Biological Statistics evolved at the University of Delaware, is very useful for biologists to choose statistical tests for validating significance (see “Relevant Websites section”).

The statistical analysis is useful in variety of biological applications. For example, [Storey and Tibshirani \(2003\)](#) used statistical significance for genomewide studies. [Cui and Churchill \(2003\)](#) reported various statistical tests for differential expression in cDNA microarray experiments, [Mitchell-Olds and Shaw \(1987\)](#) used regression analysis for biological interpretation of natural selection. Recently, [Schurch et al. \(2016\)](#) provided an insightful study for determining biological replicates to ensure valid biological interpretation of the results and which statistical tools are best for analyzing biological data.

Correlation is useful in analyzing the relationships between two biological quantities and is provided by the Pearson coefficient of correlation, typically denoted by ‘r’ (Eq. (9)).

$$r = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2} \sqrt{\sum_{i=1}^n (y_i - \bar{y})^2}} \quad (9)$$

where x and y denote the biological sample variables; $\bar{x}$ and $\bar{y}$ are respective sample means and n denotes the total number of observations.

Regression analysis is useful in cause and effect relationships as it helps in predicting the value of dependent variable (y) based on the given value of independent variable (x). Likelihood ratio of a test is used to determine the likelihood of finding a positive or negative test result, for example to determine whether a person is suffering from a diseased condition or not ([Park, 2011](#)).

Various statistical software such as R, SYSTAT, statistical package for the social sciences (SPSS), statistical analysis system (SAS), STATA, biomedical package (BMDP), etc. are useful in statistical analysis ([Tabachnick and Fidell, 1991](#)).

Final Remarks

Biological Statistics is useful in validating the significance of biological conditions and relevance (see “Relevant Websites section”). A confusion matrix is a standard tool used to evaluate the performance of a statistical classification model and various metrics including ROC curves and AUC values can be derived from the matrix. It has been recommended that the interpretation of the values of these metrics should be cautious when applied to biological domain. For example, it might be the case in which a large portion of AUC curves may fail to encode any biologically relevant results ([Scott and Barton, 2007](#); [Browne et al., 2010](#)). Given that the value of a precision depends on the prevalence of a disease, it has been argued that the precision value should not be used as a sole indicator when evaluating a diagnostic model ([Hardesty et al., 2005](#)). Along with standard evaluation techniques, some metrics specifically designed for a application domain could be also considered such as TP/FP ratio as a measure of the probability of a positive protein interaction and TP/P ratio as a measure of coverage ([Jansen et al., 2003](#)).

Handbook of Biological Statistics: Introduction.

Hypothesis Testing

Claudia Angelini, Istituto per le Applicazioni del Calcolo "M. Picone", Napoli, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

A statistical hypothesis is a statement on a population (or on several populations) and hypothesis testing is a classical and well-established framework of statistical inference (Abramovich and Ritov, 2013; Casella and Berger 2001; Lehmann, 1986; Stuart *et al.*, 2008) that allows one to decide, on the basis of an observed samples drawn from that population, which of the two complementary hypotheses to consider as true and, also, to quantify the uncertainty in this decision (Krzywinski and Altman, 2013a). For example, one can establish whether a coin is fair or not after counting the number of heads observed in a series of tosses, or one can assess whether a novel drug is more effective in lowering the cholesterol levels than an existing one, by comparing the reduction of cholesterol in two groups of individuals treated with the two drugs, and so on.

The underlying idea consists of defining an initial assumption (statistical hypothesis), observing sampled data in order to accumulate evidence in favor or against such an initial assumption, and then, given the observed data, deciding whether to reject or not reject the initial assumption.

More formally, a statistical hypothesis is an assertion regarding the distribution(s) of one or several random variables that describe the population(s). When taking a decision two complementary hypotheses are compared: the *null hypothesis* (denoted with H_0) represents the current or conventional experimental condition (e.g., the coin is fair); the *alternative hypothesis* (denoted with H_1) describes the condition one is interested to assess (e.g., the coin is not fair).

The concept of hypothesis can be rather general and may concern the parameters of the given distribution(s) (i.e., say the probability, p , of observing a head in tossing a coin) or other assumptions on the probability distribution(s) of the population(s) under study (e.g., the independence between two random variables).

The choice of which of the two hypotheses to accept is taken after performing a statistical test on samples drawn from the population(s) under study. Specifically, by looking at the value of a test statistic on the observed data, one can decide whether to accept or reject the null hypothesis. A test statistic is a random variable depending on the observations (e.g., the number of observed heads in a series of tosses) and its mathematical form depends on the specific hypotheses one is interested in. Since the value of the test statistic depends on random samples, there is a source of uncertainty in this decisional process. In particular, two types of errors might occur, i.e., rejecting the null hypothesis when it is true (*Type I error*) or accepting the null hypothesis when it is false (*Type II error*). Unfortunately, it is not possible to minimize both types of errors. Therefore, by convention one controls the probability of Type I error at some conventional (*significance*) level, α , and then, sets the decision rule accordingly. In practice, there are two ways to set a decision rule: (i) defining a *critical or rejection region* on the basis of the significance level α , and then rejecting H_0 if the observed test statistic falls in this critical regions, or (ii) computing the *p-value* for the observed data, and then rejecting H_0 if the p-value is smaller than α . Note that, roughly speaking, a rejection of H_0 is also called discovery, since usually a statistical test is designed with the aim of finding evidence for rejecting H_0 .

In brief, within the classical statistical literature, several hypothesis-testing procedures (both parametric and non parametric) have been designed to support researchers in taking suitable decisions under different experimental contexts. Such procedures have been studied in terms of their mathematical properties (i.e., power, etc.) and required assumptions (Abramovich and Ritov, 2013; Casella and Berger 2001; Lehmann, 1986; Stuart *et al.*, 2008) for a wide range of statistical hypotheses and experimental designs. Moreover, many of these tests are implemented in statistical software either as command line functions or within computational platforms with user friendly interfaces.

Nowadays, many inference problems in research areas such as genomics require simultaneously testing a large number (from hundreds to thousands or even millions) of null hypotheses (Sham and Purcell, 2014). Typical examples are the detection of differentially expressed genes from high-throughput assays such as microarrays, the identification of polymorphisms associated with a certain disease, and so on. This framework is known as *multiple comparison* (Dudoit and van der Laan, 2008; Noble, 2009) and represents one of the most widely studied research areas in the last few decades (Benjamini, 2000). In this context, different overall decision errors can be defined and adjustment procedures can be designed to control these specific error types.

In the following, we briefly summarize the key concepts and definitions related to hypothesis testing, moving from the classical approach concerning parametric tests on a single population, to non-parametric tests, to the most relevant procedures for multiple comparisons.

Background/Fundamentals

To fix the notation and introduce the general concepts, assume we have collected a random sample, $X_1, \dots, X_n$, from a population of interest, where X_i are independent and identically distributed random variables (i.e., $X_i \sim f_0(x)$, where f_0 denotes the probability density function or the probability mass function). Moreover, assume that the parameter, $\theta \in \Theta$, is unknown and that we want to perform a statistical test on its value.

The problem can be formulated as follows

$$H_0 : \theta \in \Theta_0 \text{ vs } H_1 : \theta \in \Theta_1$$

where H_0 and H_1 are the so-called *null hypothesis* and *alternative hypothesis*, respectively. The two hypotheses are complementary and mutually exclusive (i.e., $\Theta_0 \cup \Theta_1 = \Theta$ and $\Theta_0 \cap \Theta_1 = \emptyset$), with Θ_0 and Θ_1 representing the two possible values or ranges of values that the parameter θ can assume. If $\Theta_0 = \theta_0$ (or $\Theta_1 = \theta_1$), the corresponding hypothesis is said to be *simple*, otherwise the hypothesis is said to be *composite*. Examples of composite null hypotheses are $\Theta_0 \geq \theta_0$, or $\Theta_0 \leq \theta_0$ (analogously, for the alternative hypothesis). Note that in most of practical applications in biomedicine, at least one of the hypotheses is composite.

A *hypothesis testing* procedure is a decisional rule that, on the basis of the observed sample $\mathbf{x} = (x_1, \dots, x_n)$, can suggest whether to accept H_0 as true, or to reject H_0 in favor of H_1 .

In particular, to decide which of the two hypotheses to accept as true, one has to choose a function, $T(X_1, \dots, X_n)$, known as a *test statistic*, and evaluate it on the sampled data.

In many cases, large values of $t_{\text{obs}} = T(\mathbf{x}) = T(x_1, \dots, x_n)$ can be seen as a measure of the evidence against H_0 ; this means the larger $T(\mathbf{x})$ is, the less likely the observed samples were drawn under the null hypothesis. Therefore, the decision can be taken by looking at $t_{\text{obs}} = T(\mathbf{x})$.

More precisely, one can define a *critical value*, C , such that, if $T(\mathbf{x})$ is greater or equal than C , H_0 will be rejected, otherwise H_0 will be accepted (see Fig. 1, Panel a). In this set up, C divides the range of values that the test statistic, $T(X)$, can assume into two regions: an *acceptance region*, $\mathcal{A} = \{\mathbf{x} : T(\mathbf{x}) \leq C\}$, where one accepts H_0 , and a *critical or rejection region*, $\mathcal{R} = \{\mathbf{x} : T(\mathbf{x}) > C\}$, where one rejects H_0 .

It is worth noting that the partition of the decisional space into the two regions such as those reported in Fig. 1 (Panel a) has to be considered merely descriptive and it is usually associated with a so-called one-sided test. However, the symmetric partition in Fig. 1 (Panel b) could also be possible, as well as the partition shown in Fig. 1 (Panel c), which is usually associated with a so-called two-sided test.

Under the above-mentioned framework, the distributions of the test statistic under H_0 , (i.e., $P_{H_0}(T(X))$), and under H_1 , (i.e., $P_{H_1}(T(X))$), constitute the key points. In particular, we can rewrite $P_{H_0}(T(X))$ as $P_{H_0}(T(X)) = P(T(X)|H_0) = P(\text{Data}|H_0)$ where the notation $P(\text{Data}|H_0)$ has to be interpreted as the probability of the observed data assuming that H_0 is true.

Since the acceptance or the rejection of H_0 is based on the evidence collected from observed data, two types of errors might occur (Table 1): the *Type I error* (also known as the *significance level* of a test) is defined as

$$\alpha = P_{H_0}(\text{reject } H_0) = \underset{\theta \in \Theta_0}{z.drule; z.drule; raise6ptsup} P_{\theta}(T(X) \geq C) = \underset{\theta \in \Theta_0}{z.drule; z.drule; raise6ptsup} P_{\theta}(X \in \mathcal{R})$$

and the *Type II error* is defined as

$$\beta = P_{H_1}(\text{accept } H_0) = \underset{\theta \in \Theta_1}{z.drule; z.drule; raise6ptsup} P_{\theta}(T(X) < C) = \underset{\theta \in \Theta_1}{z.drule; z.drule; raise6ptsup} P_{\theta}(X \in \mathcal{A})$$

More precisely, we also define $\alpha(\theta) = P_{\theta}(X \in \mathcal{R})$ and $\beta(\theta) = P_{\theta}(X \in \mathcal{A})$

Note that Type I and Type II errors are also called the probability of false positives and the probability of false negatives, respectively.

Fig. 1 Graphical representation of acceptance and rejection regions.

Table 1 Errors in hypothesis testing

	H_0 is true	H_1 is true
Decision: Accept H_0	Correct decision $1-\alpha$	Type II error β
Decision: Reject H_0	Type I error α	Correct decision $\pi = 1-\beta$

Then, the *power* of a test, as function of θ , is given by

$$\pi(\theta) = \begin{cases} \alpha(\theta) & \theta \in \Theta_0 \\ 1 - \beta(\theta) & \theta \in \Theta_1 \end{cases},$$

and it represents the probability of rejecting H_0 , or equivalently, the probability of discovering H_1 when it is true.

In principle, the critical value of C should be chosen to minimize the two error types. Unfortunately, it is not possible to simultaneously minimize both types of errors, since when one error decreases the other increases. Moreover, when the alternative is composite, it is difficult to compute P_{H_1} (accept H_0) and then to minimize the sums of the two errors. Therefore, the classical approach to hypothesis testing suggests choosing C so as to guarantee that the Type I error is below a prespecified significance level, α .

Typical significance levels are $\alpha = 0.05$ or $\alpha = 0.01$, although such choices are rather conventional (Wasserstein and Lazar, 2016 and therein). Indeed, the choice of the actual significance level α to be used in a test depends on the impact that false positives have in that specific context, and has to be decided before observing the data.

Significance, power and sample size are strongly interplaying factors in hypothesis testing (Efron, 2007; Krzywinski and Altman, 2013b,c; Nuzzo, 2016), and not accounting for such relationships can lead to incorrect results, waste of resources, and other ethical issues (Ioannidis, 2005). For example, on the one hand, for a fixed sample size, n , decreasing the significance level, α , (say, from 0.05 to 0.01) results in a loss of power for the testing procedure. The lack of power implies that many small effects might not be detected (false negatives) by the testing procedure, and usually only the strongest effects are detected. On the other hand, for a fixed significance level, α , increasing the sample size, n , produces an increase in power. Therefore, balancing sample size, significance, and power becomes a crucial part of experimental design, in particular in omics studies (Krzywinski and Altman, 2013c; Sham and Purcell, 2014).

Another important concept in hypothesis testing is the *p-value*, which can be defined as

$$p\text{-value} = P_{H_0}(T(X)) = t_{\text{obs}} \text{ or } T(X) \text{ more extreme than } t_{\text{obs}} \text{ assuming } H_0 \text{ hold}$$

that is, the probability (under the null hypothesis) of observing a test statistic equal or even more extreme than the one observed on the sample x . Unfortunately, in the so-called “*prosecutor’s fallacy*,” the *p-value* is often misinterpreted as the probability that H_0 is true (Altman and Krzywinski, 2017a,b; Greenland et al., 2016; Krzywinski and Altman, 2013b; Nuzzo, 2015), while it is only a measure of evidence against the null hypothesis. In practice, the smaller the *p-value*, the more “unlikely” the observed data come from the null hypothesis. Therefore, one can still reject H_0 if the *p-value* is smaller or equal to the significance level, α , but he/she has to remember that $P(\text{Data}|H_0) \neq P(H_0|\text{Data})$. In particular, while $P(\text{Data}|H_0)$ is related to the concept of *p-value*, $P(H_0|\text{Data})$ is a posterior probability that is not evaluated within the classical statistical framework. In order to define $P(H_0|\text{Data})$, one has to redefine mathematical hypothesis testing within the Bayesian statistical framework (Berger, 1985).

Systems and/or Applications

The formulation of a statistical hypothesis test can be generalized to more than one statistical population (Krzywinski and Altman, 2014b). However, while the formalism and the definitions do not change, the way in which is possible to design the statistical experiment (i.e., the type of hypothesis and the data collection) might lead one to distinguish different testing procedures. For example, when testing whether two populations have or do not have the same mean, one has to distinguish whether the experimental design is independent or paired. In the case of paired samples, instead of the simple one-sample T-test, one can consider the two-sample T-test, then (depending on the experimental design (Krzywinski and Altman, 2014a)) an independent two-sample T-test, or a paired-two-sample T-test. In the same scenario, when there are more than two populations, the F-test within the ANOVA model could be considered. Obviously, the T-test requires the data to be normally distributed. If such an assumption is not satisfied, non-parametric tests (such as, for example, the Mann–Whitney–Wilcoxon test) have to be considered.

More formally, within hypothesis testing we can distinguish two types of tests: parametric tests and nonparametric tests (Krzywinski and Altman, 2014d).

Parametric Tests

A parametric hypothesis test assumes that observed data are distributed according to distributions of a well-known form (e.g., normal, binomial, and so on) up to some unknown parameter(s) on which we want to make inferences (say the mean, or the success probability). Examples of this type of test are the T-test for comparing mean(s), the binomial test for comparing proportions, and the F-test for ANOVA models, among many others. It is important to understand that the validity of a parametric test depends on the assumptions one can make about the underlying population(s). If the assumptions are satisfied, then the decision rule will control the Type I error at the chosen significance level. Otherwise, the results may be over-optimistic and the decision may not be taken under proper error control. In the case of the classical T-test, the samples, $X_1, \dots, X_n$, are assumed to be drawn from normal populations, with the same variance and that they are uncorrelated. Corrections such as Welch's variant have to be applied in case of unequal variances.

Nonparametric Tests

A nonparametric test is a hypothesis test where it is not necessary (or not possible) to specify the parametric form of the distribution(s) of the underlying population(s). Therefore, they require few assumptions about the population under study, and can be used to test much wider cases of possibilities. Examples of this type of test include the sign test, Mann-Whitney-Wilcoxon test, Chi-square test, Kruskal-Wallis test, and the Kolmogorov-Smirnov test, among many others.

Hypothesis Testing and Other Statistical Approaches

It should be noted that statistical hypothesis testing procedures are not only interesting in their own right, but they can be also combined with other inferential statistical procedures such as regression analysis, model/variable selection, and so on. For example within linear regression, the significance of a specific regression coefficient can be assessed by a hypothesis test.

Testing Procedure Step-by-Step

A testing procedure involves the following steps:

1. Formulate the two hypotheses: the null hypothesis H_0 and the alternative hypothesis H_1 :
2. Decide the significance level, α , for the test.
3. Choose the test statistic, $T(X)$, on the basis of the hypothesis to be tested and the assumptions about the data probability distribution.
4. For the given significance level, α , calculate the critical value, C , of the test statistic under H_0 . Then, deduce the critical region, $\mathcal{R}$, or the acceptance region, $\mathcal{A}$.
5. Collect your data X and compute the observed test statistic $t_{\text{obs}} = T(x)$
6. Take the decision to accept or to reject the null hypothesis on the basis of t_{obs} as follows: if t_{obs} is located in the critical region $\mathcal{R}$, then reject the null hypothesis, H_0 , in favor of the alternative hypothesis H_1 , otherwise accept H_0 .

When the p-value approach is used, after above steps (1)–(3) one has to

4. Collect your data and compute the observed test statistics t_{obs}
5. Compute the *p-value* associated with t_{obs}
6. Take the decision to accept or to reject the null hypothesis on the basis of the *p-value* as follows: if *p-value* $< \alpha$, then reject the null hypothesis, H_0 , in favor of the alternative hypothesis H_1 , otherwise accept H_0 .

Results, Discussion and Advanced Approaches

Reporting Results and Misinterpretation of p-Values

In order to report the result of a statistical test, one should explicitly formulate the null and the alternative hypotheses, the test statistic that was used, and the p-value observed on the sample data. As previously stated, the p-value is one of the most misinterpreted concepts in statistics (Altman and Krzywinski, 2017a,b; Nuzzo, 2015, among many others), in particular in biomedical science. Indeed, in the last few years there has been an increasing debate in the statistical community on the misuse of the p-value concept in many scientific publications (Halsey *et al.*, 2015; Huber, 2016; Lazzeroni *et al.*, 2016; van Helden, 2016, among many others). The reason is that a small p-value is often associated with the possibility of publishing a result. Therefore, there has been increasing attention paid to its value. Although a small p-value can be seen as a measure of evidence against the null hypothesis, a small p-value can also be observed in a poorly designed study or when the test assumptions are violated, hence the p-value alone is not sufficient to guarantee good reproducibility of the findings (Ioannidis, 2005).

Additionally, it is important to remember that the *p-value* of a given test is computed from the observed data assuming that H_0 is true (i.e., it is related to $(Data|H_0)$), regardless of the form of the alternative hypothesis, H_1 , hence it does not provide support

for the alternative. Finally, $P(\text{Data}|H_0) \neq P(H_0|\text{Data})$, where $P(H_0|\text{Data})$ denotes the (posterior) probability that H_0 is true. Therefore, the p-value is not the probability that the null hypothesis is true. To better understand these points (Greenland *et al.*, 2016) provided a guide to properly reporting and interpreting the p-values.

Multiple Hypothesis Testing

To fix notations and introduce the general concepts, suppose that one is interested in performing a series of M simultaneous tests where the null hypotheses, H_{0i} , are compared with H_{1i} , as follows

$$H_{0i} : \theta_i \in \Theta_{0i} \text{ vs } H_{1i} : \theta_i \in \Theta_{1i} \quad i = 1, \dots, M.$$

Such circumstances are typical of many omics studies (Sham and Purcell, 2014), where the number of comparison, M , can be as large as thousands, hundreds of thousands or even more. In these cases, the use of p-values and/or individual decisional rules can result in a series of uncontrolled errors (Krzywinski and Altman, 2014c; Noble, 2009). In fact, suppose that one decides to apply an individual testing procedure at the same significance level, α , to each of the M tests, then the probability of “not making any Type I error in M tests” is $(1 - \alpha)^M$, (≈ 0 when M increases) and hence the probability of “taking at least a wrong rejection in M ” tests is $1 - (1 - \alpha)^M$, (≈ 1 when M increases). Not only that, by applying an individual testing procedure, it is expected to have on average $M\alpha$ false discoveries in M tests.

More precisely, as depicted in Table 2, we can assume that out of M tested null hypotheses, H_{0i} , M_0 are true (hence $M - M_0$ are false). M is known, while M_0 is an unknown parameter. In the decisional process we can reject R null hypotheses, (hence, $M - R$ hypotheses will be accepted). Out of the R discoveries, let S denote the number of true discoveries and V the number of false positives. Out of the $M - R$ accepted null hypotheses, let U denote the number of correctly accepted null hypotheses and T the number of false negatives. R is an observable random variable; V , S , U and T are not observable variables.

Several global measures of errors can be defined (Dudoit *et al.*, 2004a,b; Dudoit and van der Laan, 2008).

For the sake of brevity we report here only FWER (family wise error rate) and FDR (false discovery rate), that are defined as follows:

$$\text{FWER} = P(V \geq 1) = P(\text{at least one false positive discovery})$$

$$\text{FDR} = E[V/R] = E[V/(V + S)], \text{ where } E[\cdot] \text{ denotes the expected value of the random variable.}$$

Out of these error types, FDR (originally proposed in Benjamini and Hochberg (1995)) has had a significant impact in genomics since it better compromises between false positives and false negatives when the number of hypotheses to be tested is very large. For each of these global error types, there are several controlling procedures for guaranteeing the overall error is kept below some pre-specified significance level, α .

Bonferroni Correction

In order to guarantee that $\text{FWER} \leq \alpha$, one can test each hypothesis (H_{0i} versus H_{1i}) at the individual significance level, $\alpha' = \alpha/M$. Equivalently, one can define the so-called *adjusted p-values* defined as

$$p_i^{\text{adj}} = \min(1, Mp_i)$$

where p_i is the p-value of the i -th test, and then reject only those hypotheses, H_{0i} , such that $p_i^{\text{adj}} \leq \alpha$.

Benjamini and Hochberg Correction

In order to guarantee that $\text{FDR} \leq \alpha$, one can use the BH step-up procedure, which works as follows:

1. Order the individual p-values, $p_{(i)}$, from smallest to largest
 $p_{(1)} \leq p_{(2)} \leq \dots \leq p_{(M)}$, where $p_{(i)}$ denotes the i -th ordered p-value.
2. Find the largest k such that $p_{(k)} \leq \frac{k}{M}\alpha$
3. If $k > 0$, reject the null hypotheses $H_{0(1)}, \dots, H_{0(k)}$, otherwise accept all null hypotheses.

Table 2 Errors in multiple hypothesis testing

	# true Null hypotheses	# true Alternative hypotheses	# total hypotheses
# Accepted null hypotheses	U	T	M-R
# Rejected null hypotheses	V	S	R
Total	M_0	$M - M_0$	M

Springer Series in Statistics.

The corresponding *adjusted p-values* are defined as $p_i^{adj} = \min\left(\frac{M \cdot p_{(i)}}{i}, 1\right)$.

The above-mentioned BH procedure requires that the M tests are independent, variants of such a correction procedure are available under dependency (Benjamini and Yekutieli, 2001). Moreover, it can be proved that the BH controlling procedure assures that $FDR \leq (M_0 / M) * \alpha \leq \alpha$. If $M_0 \ll M$ (as in the case of microarray or RNASeq data analysis), the procedure could be suboptimal, and an adaptive procedure can be used in order to improve the overall power (Benjamini *et al.*, 2006).

Other Procedures and Error Types

After the seminal paper concerning FDR (Benjamini and Hochberg, 1995), several related concepts and controlling procedures have been proposed, such as pFDR (Storey, 2002, 2003), and fdr (Efron, 2008), among many others. As for individual testing procedures, many of these controlling procedures are implemented in available statistical software (Dudoit and van der Laan, 2008; Bretz *et al.*, 2011) and are of common used when analyzing omic data. However, although the general idea behind such methods is similar, there could be important differences either in the choice of the global decisional errors and in the type of procedures used to keep such error under control (see, Benjamini, 2000, and discussion therein).

Future Directions

Large-scale hypothesis testing is a typical problem faced when analyzing biomedical data. In particular, the analysis of omic data is challenged by the fact that hundreds of thousands or even millions of hypotheses have to be compared, and only a limited number of samples can be collected (often referred to as a large p small n situation). Moreover, the data (e.g., gene expression) are usually highly correlated and parametric assumptions may not be satisfied. The problem is particularly relevant when hypothesis testing becomes part of more comprehensive inferential procedures, such as regression, model selection, and dimension reduction. To face such challenges, high dimensional testing procedures in complex experimental designs still have to be improved.

Closing Remarks

Hypothesis testing constitutes one of the most studied topics in modern statistical inference, with several applications in the analysis of biomedical data, since it allows one to study the effect of a certain drug in a group of individuals, to monitor gene expression under different conditions, to detect genomic variants associated with a certain pathology, and so on. The key concept is to support researchers in choosing (on the basis of observed data) between two possibilities, and to quantify the uncertainty in this decisional process by means of the two types of errors. Results are often reported in terms of p -values, and adjustment procedures have to be applied when multiple hypotheses are compared (Noble, 2009). Recently the American Statistical association has produced a statement on the way in which p -values should be reported and interpreted (Wasserstein and Lazar, 2016, and reference therein) in order to avoid misinterpretation and incorrect results (Ioannidis, 2005).

Introduction

A common bioinformatics problem is to determine, in terms of probability, whether an observed sample is drawn from a specific population (i.e., distribution). Another common situation is to decide whether differences between two or more groups of samples are due to the differences in the populations or matter of chance. All such kind of problems can be stated in terms of a statistical hypothesis test as described in many standard statistical book (Abramovich and Ritov, 2013; Casella and Berger, 2001; Ross, 2009) among many others.

In this article, we present the most commonly used statistical inference techniques, trying to organize them in a simple way for quick consultation. The plethora of hypothesis tests available in the modern statistics can be divided essentially into two categories: parametric and nonparametric. The first category includes those tests based on the assumption of knowing the distribution of the underlying population(s) up to some unknown parameters; the second category contains those tests that are “distribution-free”. When a parametric test is used, then it must be stated that “If the assumptions regarding the shape of the population(s) are valid, then we conclude...”, on the other hand if the same conclusions are drawn using a nonparametric test it is enough to state that “regardless of the shape of the population we may conclude that...”. At a first glance, it seems that nonparametric tests are preferable to parametric ones, however this is not always the case, because when the assumptions are met, then a parametric test is always more powerful than a nonparametric one. Hence, as a rule of thumb, it is a good practice to use a parametric test instead of a nonparametric one when assumptions are satisfied. Moreover, the validity of the assumptions can be tested.

With this distinction in mind, this article is divided in two sections: parametric tests and nonparametric tests. Inside each section, the techniques are assigned to subsections according to the experimental design for which they are appropriate. Specifically, each section is divided into three subsections: the first containing techniques employed when one statistical sample is available, the second containing techniques employed when two statistical samples are available, the last one containing techniques employed when more than two statistical samples are available. Fig. 1 summarizes these different experimental designs.

We use classical notations as described in Casella and Berger (2001) and adopt the p-value approach. Hence, for each test, we present the model assumptions and its test statistics, being the evaluation of the p-value demanded to common statistical software. All the tests discussed in this article along with their respective built in functions in Matlab and R are summarized in Table 1.

Parametric Tests

A parametric test is a hypothesis testing procedure based on the assumption that observed data are distributed according to some distributions of well-known form (e.g., normal, Bernoulli, and so on) up to some unknown parameter(s) on which we want to make inference (say the mean, or the success probability). Examples of this type of test are the T-test for comparing the mean(s), the Binomial test for comparing the proportions, the F-test for the ANOVA models. It is important to understand that the validity of a parametric test depends on the assumptions one can elicit on the underlying population(s). If the assumptions are satisfied, then the decision rule will control the Type I error at the chosen significance level. Otherwise, results might be over-optimistic and the decision might not be under a proper error control.

Fig. 1 Sketch of experimental data in one sample design (A); two samples design (B1 and B2); K-samples design (C).

Table 1 Most common hypothesis testing procedures and respective built in Matlab and R functions

Test	decription	Name of Matlab function	Name of R function
T-test	Tests if a gaussian sample with unknown variance has a specified mean	ttest	t.test
Binomial test	Tests if a Bernoulli sample has a specified success probability	cdf('bino',...); ztest	binom.test
Two sample T-test	Tests if two gaussian samples have the same mean	ttest2	t.test
Fisher-Irwin	Tests if two Benoulli samples have the same success probability	cdf('hyge',...); ztest	prop.test
One-way ANOVA	Tests if multiple gaussian samples have the same mean	anova1	oneway.test
Sign test	Tests if an ordinal sample has a specified median	signtest	binom.test
Signed Rank test	Tests if a continuos sample is symmetric around a specified median	signrank	wilcox.test(one-sample)
One-sample chi-square	Tests if a sample fits a specified discrete probabilistic model	chi2gof	chisq.test
One-sample Kolmogorov-Smirnov	Tests if a sample fits a specified continuos probabilistic model	kstest	ks.test
Shapiro-Wilk	Tests if a sample fits a gaussian distribution	swtest	shapiro.test
Mann-Whitney	Tests if two samples have the same median	ranksum	wilcox.test(two-sample)
Chi-square test of independence	Tests if two characteristics are independent	cdf('chi2',...)	fisher.test
Two-sample Kolmogorov-Smirnov	Tests if two samples come from the same continuous distribution	kstest2	ks.tests
Kruskal-Wallis	Tests if multiple samples have the same median	kruskalwallis	kruskal.test

Statistical Tests for the “One-Sample” Case

Assume we have collected a random sample $X_1, \dots, X_n$ from a population of interest, where X_i are independent and identically distributed random variables (i.e., $X_i \sim f_\theta(x)$, with f denoting the probability distribution function). See [Fig. 1\(A\)](#).

One sample T-test

This test allows making inference on the mean of a given normal population.

Under the hypothesis that $f_\theta(x)$ follows a Gaussian distribution, with unknown parameters $\vartheta = (\mu, \sigma^2)$, the one-sample T-test is used to determine whether our sample has a given mean $\mu = \mu_0$ (i.e., $H_0: \mu = \mu_0$ vs $H_1: \mu \neq \mu_0$) or if our sample has a mean not smaller than a given value (i.e., $H_0: \mu \geq \mu_0$ vs $H_1: \mu < \mu_0$) or if our sample has a mean not larger than a given value (i.e., $H_0: \mu \leq \mu_0$ vs $H_1: \mu > \mu_0$). In all cases, the test statistics results to be:

$$T(X_1, \dots, X_n) = \frac{\bar{X} - \mu_0}{S/\sqrt{n}}, \text{ with}$$

$$\bar{X} = \sum_{i=1}^n X_i/n \quad \text{and} \quad S^2 = \frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X})^2$$

denoting the sample mean and sample variance, respectively.

Under the null hypothesis, the test statistics is distributed like a T-Student variable with $n - 1$ degree of freedom. Hence, the test is called T-test.

The one-sample T-test appears in many bioinformatics contexts, such as measuring protein expression, the quantity of drug delivered by a medication and so on; since its central role in inference all statistical software have a built in T-test function, see [Krzywinski and Altman \(2013\)](#) for more discussion. [Table 2](#) summarizes the p-values for each of the three hypothesis tests, with T_{n-1} denoting a Student variable and t_{obs} the observed value of the test statistics.

Finally, let us note that when the sample size is sufficiently large (usually $n \geq 30$), then this test can be applied without the normality assumption by the mean of the Central Limit Theorem.

Table 2 p -values for the one-sample T -test; the test statistics being a Student variable.

H_0	H_1	p -Value
$\mu = \mu_0$	$\mu \neq \mu_0$	$2P(T_{n-1} > t_{obs})$
$\mu \geq \mu_0$	$\mu < \mu_0$	$P(T_{n-1} < t_{obs})$
$\mu \leq \mu_0$	$\mu > \mu_0$	$P(T_{n-1} > t_{obs})$

Table 3 p -values for the binomial test; the test statistics being a Binomial variable.

H_0	H_1	p -value
$p = p_0$	$p \neq p_0$	$2 \min\{P(T \geq t_{obs}), P(T \leq t_{obs})\}$
$p \geq p_0$	$p < p_0$	$P(T < t_{obs})$
$p \leq p_0$	$p > p_0$	$P(T > t_{obs})$

Binomial test

This test allows making inference on the success probability of a given Bernoulli population. Under the hypothesis that the underling population is Bernoulli distributed, with unknown $p = P(X=1)$, then it is possible to test whether our sample has a given probability of success p_0 (i.e., $H_0: p = p_0$ vs $H_1: p \neq p_0$) or if our sample has a probability of success not smaller than a given value (i.e., $H_0: p \geq p_0$ vs $H_1: p < p_0$) or if our sample has a probability of success not larger than a given value (i.e. $H_0: p \leq p_0$ vs $H_1: p > p_0$). In all these cases, the test statistics results to be:

$$T(X_1, \dots, X_n) = \sum_{i=1}^n X_i.$$

Under the null hypothesis, the test statistics T is distributed like a Binomial random variable with number of trials n (the sample size) and probability of success p_0 , denoted $B(n, p_0)$. This test is known as the Binomial test and the p -value is evaluated according to **Table 3** with T distributed as a $B(n, p_0)$ variable and t_{obs} the observed value of the test statistics.

Finally, we observe that, when $np_0(1-p_0) > 20$, the Binomial distribution is well approximated by a Gaussian one, then evaluation of the p -value simplifies and the test is known as approximated Binomial test.

Statistical Tests for the “Two-Sample” Case

The two-sample statistical tests are used when the researcher wishes to establish whether two treatments are different, or whether one treatment is “better” than another. The treatments can be any diverse variety of conditions and the two samples come from two groups that underwent to two different conditions. Two different experimental designs can be used for this aim: the paired experimental design, where the two samples have the same number of data and each member of the first sample is connected to a specific member of the second sample serving as its own control, and the independent experimental design, where the members of the two groups are independent and the sample sizes might be different. Sketch of these experimental designs are shown in **Fig. 1 (B1)** and **(B2)**, respectively.

Paired two-samples T -test

This test allows making inference on the means of two normal populations when the sampling design is paired.

Under the assumption that the pairs $\{(X_i, Y_i)\}_{i=1, \dots, n}$ are sampled from two Gaussian distributions with unknown mean, μ_1 and μ_2 , and unknown variance (not necessarily the same), it is easy to show that the problem reduces to the one-sample T -test applied to the data $\{W_i = (X_i - Y_i)\}_{i=1, \dots, n}$ for testing $H_0: \mu_1 - \mu_2 = 0$ vs $H_1: \mu_1 - \mu_2 \neq 0$; or for testing $H_0: \mu_1 - \mu_2 \geq 0$ vs $H_1: \mu_1 - \mu_2 < 0$; or $H_0: \mu_1 - \mu_2 \leq 0$ vs $H_1: \mu_1 - \mu_2 > 0$. The test statistics is $T(W_1 \dots W_n) = \sqrt{n} \bar{W} / S_W \sim T_{n-1}$, with $\bar{W}$ and S_W the sample mean and the sample variance of $\{W_i\}_{i=1, \dots, n}$. Under H_0 , the test statistics is distributed like a T -student with $n-1$ degree of freedom and the p -value is evaluated according to **Table 2**.

Independent two-samples T -test

This test allows making inference on the means of two normal populations when the sampling design is independent.

Under the assumption that the data $X_1, \dots, X_n$ and $Y_1, \dots, Y_m$ are sampled from two independent Gaussian distributions with unknown mean, μ_1 and μ_2 , and unknown equal variance σ^2 , it is possible to test $H_0: \mu_1 - \mu_2 = 0$ vs $H_1: \mu_1 - \mu_2 \neq 0$, or $H_0: \mu_1 - \mu_2 \geq 0$ vs $H_1: \mu_1 - \mu_2 < 0$ or $H_0: \mu_1 - \mu_2 \leq 0$ vs $H_1: \mu_1 - \mu_2 > 0$. The test statistics results to be:

Table 4 p -values for the independent two-sample T -test; the test statistics being a Student variable.

H_0	H_1	p -value
$\mu_1 = \mu_2$	$\mu_1 \neq \mu_2$	$2P(T_{n+m-2} > t_{obs})$
$\mu_1 \geq \mu_2$	$\mu_1 < \mu_2$	$P(T_{n+m-2} < t_{obs})$
$\mu_1 \leq \mu_2$	$\mu_1 > \mu_2$	$P(T_{n+m-2} > t_{obs})$

	Group 1	Group 2
Number of success	$\sum_{i=1}^n X_i = n_1$	$\sum_{i=1}^m Y_i = m_1$
Number of failures	$n - n_1$	$m - m_1$
Sample size	n	m

Fig. 2 Contingency table for the Fisher-Irwin test.

$$T(X_1, \dots, X_n, Y_1, \dots, Y_m) = \frac{\bar{X} - \bar{Y}}{S_p \sqrt{1/n + 1/m}}, \text{ where}$$

$$\bar{X} = \sum_{i=1}^n X_i/n, S_X^2 = \frac{1}{n-1} \sum_{i=1}^n (X_i - \bar{X})^2; \quad \bar{Y} = \sum_{i=1}^m Y_i/m, S_Y^2 = \frac{1}{m-1} \sum_{i=1}^m (Y_i - \bar{Y})^2$$

and the pooled variance is defined by $S_p = ((n-1)S_X^2 + (m-1)S_Y^2)/(n+m-2)$.

Under the null hypothesis, the test statistics has a Student distribution with $n+m-2$ degree of freedom and [Table 4](#) reports the p -value for each situation.

See [Ross \(2009\)](#), [Krzywinski and Altman \(2014b,c\)](#) for more details and discussion. Further, we stress that when the hypothesis of equal variance is not met, then the Welch's modification can be applied ([Lehmann 1999](#)). The test statistics is given by:

$$T(X_1, \dots, X_n, Y_1, \dots, Y_m) = \frac{\bar{X} - \bar{Y}}{\sqrt{S_X^2/n + S_Y^2/m}}$$

and it results to be again a Student variable T_ν with degree of freedom given by the following formula, $(\nu) = (S_X^2/n + S_Y^2/m^2)/(S_X^4/n^2(n-1) + S_Y^4/m^2(m-1))$. In all the common statistical software, the two-independent t-test is built in with the options equal or unequal variance.

Finally, let us note that when the samples' size are sufficiently large (usually $n, m \geq 30$), then both paired and independent two-sample T-test can be applied without the normality assumption by the mean of the Central Limit Theorem.

Fisher-Irwin test

This test allows making inference on the success probability parameters of two Bernoulli populations.

Suppose a research has scores from two independent samples all falling into one or the other of two mutually exclusive classes. In other words, suppose the researcher has two groups, experimental and control, or female and male, or with disease and not-disease, and for each group the experimenter measures a dichotomous variable. Then, the two groups of scores $X_1, \dots, X_n$ and $Y_1, \dots, Y_m$ can be assumed to be sampled from two independent Bernoulli distributions with unknown parameter p_1 and p_2 . [Fig. 2](#) outlines the type of data in this specific case. The Fisher-Irwin test serves to test the hypothesis $H_0: p_1 = p_2$ vs $H_1: p_1 \neq p_2$, and it is based on a statistics whose distribution under H_0 is exactly known to be hypergeometric. Sometimes this test is also presented as a nonparametric test because it can be adapted to several other situations when data are discrete (nominal or ordinal), however according to our definition the test assumes the data distribution known except for two parameters about which the hypothesis is formulated. See [Ross \(2009\)](#) for more details. Finally, we note that when the size of the two samples are large, then it is possible to approximate the Binomial variables $\sum_{i=1}^n X_i$ and $\sum_{i=1}^m Y_i$ with Gaussian variables and evaluation of p -value simplifies. See [Ross \(2009\)](#) and [Siegel \(1956\)](#) for more details and one-tail situations.

Statistical Tests for k Samples

The k-samples statistical test is used when the researcher wishes to establish if k groups, that underwent k different conditions, are different. See Fig. 1(C) for an experimental design sketch. The case $k=2$ falls into the two-sample T-test, then here we suppose $k>2$. The ANOVA model furnishes a well known parametric test when the k samples are supposed to come from Gaussian distributions with unknown means $\mu_1, \mu_2, \dots, \mu_k$ and unknown (necessarily) common variance σ^2 .

One-way ANOVA

This test allows making inference on the means of more than two normal populations.

Assume we have collected a sample $X_{i1}, \dots, X_{ini}$ from $N(\mu_i, \sigma^2)$ for each condition $i=1, \dots, k$ and assume we want to test $H_0 : \mu_1 = \mu_2 = \dots = \mu_k$ (i.e., the mean in all groups is the same) versus the alternative hypothesis that H_0 is not true (at least one group's mean is different). If the k samples have the same size, $n_1 = n_2 = \dots = n_k$ the model is called balanced; otherwise the model is called unbalanced. In both cases, the test statistics is the following:

$$T(\dots X_{ij} \dots) = \frac{SS_b/k-1}{SS_w/N-k}$$

with $N = \sum_{i=1}^k n_i$ and where SS_b denotes the so called *Between groups Sum of Squares* and SS_w the *Within group Sum of Squares* defined as:

$$SS_b = \sum_{i=1}^k n_i (X_{i*} - X_{**})^2 \quad \text{and} \quad SS_w = \sum_{i=1}^k \sum_{j=1}^{n_i} (X_{ij} - X_{i*})^2$$

In this notation, the symbol * stands for the empirical mean with respect to the variable *, (for example $X_{3*} = \frac{1}{n_3} \sum_{j=1}^{n_3} X_{3j}$). The test statistics makes a comparison between two different estimators of σ^2 , $SS_w/N - k$ which is always a good estimator of σ^2 and $SS_b/k - 1$ which is a good estimator of σ^2 when H_0 is true, while it tends to overestimate σ^2 when H_0 is not true. This observation implies that the larger the observed statistic the more likely the observed scores did not come from the population described by the null hypothesis. Under the null hypothesis, the test statistics is distributed like a Fisher variable with $k - 1$ degree of freedom at the numerator and $N - k$ degree of freedom at the denominator, the p-value results to be $P(F_{k-1, N-k} > t_{obs})$, where $F_{k-1, N-k}$ is a Fisher variable and t_{obs} is the observed value of the test statistics.

If there is a significant difference between the groups, further tests (known as *post hoc tests*) are performed to verify which groups are really different from each other, see Klockars and Hancock (2000) for more details.

When possible the balanced scenario is always preferable to the unbalanced scenario since it is more robust with respect to departure from the hypothesis.

Finally, we observe that the one-way ANOVA model allows you to study the effect of a single factor on data distribution, i.e. it determines whether the group's average is influenced by belonging to the group. It is also possible to study the effect of two factors simultaneously using the two-way ANOVA model that lets you determine whether the average of the groups is affected by either of the two factors. This last model can be used with or without interactions and for a more complete discussion we demand to Krzywinski and Altman (2014b,c), Ross (2009), and Casella and Berger (2001).

Nonparametric Tests

Nonparametric tests are hypothesis testing procedures where it is not necessary (or not possible) to specify the parametric form of the underlying population(s) distribution(s). Therefore, they require few assumptions on the population under study and can be used to test much wider ranges of possibilities. Moreover, many nonparametric tests adapt to the case of ordinal and categorical random variables, for the first type of data being possible to evaluate the rank, for the second type of data being possible to evaluate only frequencies of occurrence.

Examples of this type of such tests include the sign test, Mann-Whitney-Wilcoxon test, Chi-square test, Kruskal-Wallis test, Kolmogorov-Smirnov test, among many others.

Statistical Tests for the “One-Sample” Case

Sign test

This test allows making inference on the median of a population.

Suppose we have a random sample $X_1, \dots, X_n$ extracted from an unknown population with an unknown median m . The sign test is used to test the hypothesis $H_0: m = m_0$ vs $H_1: m \neq m_0$. The data are supposed to be at least of ordinal type so that for each X_i it is possible to evaluate the following sign function:

$$I_i = \begin{cases} 1 & \text{if } X_i < m_0 \\ 0 & \text{if } X_i \geq m_0 \end{cases}$$

Under the null hypothesis, the new random variables $I_1, \dots, I_n$ are independent Bernoulli variables with probability of success $1/2$. It is then possible to apply the Binomial test presented in Section Statistical Tests For The "One-Sample" Case for evaluating the p-value of the test statistics $T(X_1, \dots, X_n) = \sum_{i=1}^n I_i$, which is called sign sum statistics. See Siegel (1956), Ross (2009), Krzywinski and Altman (2014a).

Signed rank test

This test allows making inference on the symmetry of a distribution around its median. Suppose we have a random sample $X_1, \dots, X_n$ extracted from an unknown continuous population with unknown median m . The signed rank test is used to test the hypothesis $H_0 : P(X < m_0 - a) = P(X \geq m_0 + a) \forall a > 0$ vs H_1 : the population is not symmetric around its median. While, the sign test serves to test the hypothesis that the population is centered around m_0 , using only the information if the data is smaller or bigger than m_0 ; the signed rank test serves to test the hypothesis that the population is centered and symmetric around m_0 , using the information how much the data is smaller or bigger than m_0 .

Define $Y_i = X_i - m_0$, for $i = 1, \dots, n$, and rank all the Y_i 's without regard to sign: give rank 1 to the smallest $|Y_i|$, give rank 2 to the next smallest $|Y_i|$, etc. Like in the sign test define for each $i = 1, \dots, n$ the sign function $I_i = \begin{cases} 1 & \text{if } X_i < m_0 \\ 0 & \text{if } X_i \geq m_0 \end{cases}$ and sum the rank having a sign equals 1, i.e. sum the rank of the observations $X_i < m_0$, the test statistics results to be:

$T(X_1, \dots, X_n) = \sum_{i=1}^n I_i \text{rank}(|Y_i|)$, the sum of rank statistics. Evaluation of the p-value is demanded to standard statistical software. See Ross (2009) for more details.

One-sample chi-square test

This test is as goodness of fit test, i.e. it is used for verifying whether the data fit a given discrete probabilistic model.

Suppose the researcher is interested in the number of subjects, objects or responses, which fall in various categories. For example, a group of patients can be classified according to their response to a certain drug: "good", "indifferent", "bad", and the researcher is interested in testing the hypothesis that the frequencies of these three categories of response is equal to some putative frequencies. The number of categories may be $k \geq 2$, however the case $k=2$ results in the above-mentioned Binomial test. This test is a non-parametric test, since data are supposed to be sampled from an unknown discrete population with unknown expected frequencies for the k categories and one wants to test $H_0 : (p_1, \dots, p_k) = (p_1^0, \dots, p_k^0)$ vs $H_1 : (p_1, \dots, p_k) \neq (p_1^0, \dots, p_k^0)$.

Let us denote O_i the observed number of data categorized into i -th category, i.e., $O_i = \sum_{j=1}^n \text{Ind}(X_j = i)$ with $\text{Ind}(A) = 1$, if A is true; 0 otherwise, and denote $E_i = np_i^0$ the expected number of data into i -th category under H_0 ; then the test statistics is defined by the following expression

$$\chi^2(X_1, \dots, X_n) = \sum_{i=1}^k \frac{(O_i - E_i)^2}{E_i}$$

Under the null hypothesis is possible to show that the test statistics is distributed like a χ_{k-1}^2 with $k-1$ degree of freedom.

The p-value results to be $P(\chi_{k-1}^2 > t_{\text{obs}})$; roughly speaking, the larger the observed statistic the more likely the observed frequencies did not come from the population described by the null hypothesis. This test is valid when the expected number of data falling into category i , E_i , satisfy the hypothesis that at least 80% of them are such that $E_i \geq 5$ and at least 20% of them are such that $E_i \geq 1$. See Siegel (1956), Ross (2009) for more details and examples.

One-sample Kolmogorov-Smirnov test

This test is as goodness of fit test, i.e. it is used for verifying whether the data fit a given continuous probabilistic model.

Suppose we have a sample $X_1, \dots, X_n$ of scalar values and suppose we want to test the hypothesis that this sample is drawn from a putative distribution $F_0(x)$. Then, if $F_X(x)$ is the cumulative distribution function of the sampled random variable, we want to test $H_0: F_X = F_0$ vs $H_1: F_X \neq F_0$. The rationale behind this test consists in evaluating the empirical cumulative distribution and computing the greatest difference between observed and expected cumulative distribution functions. More specifically, if $F_e(x) = \frac{1}{n} \sum_{i=1}^n \text{Ind}(X_i \leq x)$ is the empirical cumulative distribution function (i.e., based on the observed values), the test statistic is the maximum deviation between them, $D = \max_{-\infty < x < +\infty} |F_e(x) - F_0(x)|$. The larger the observed statistic, d_{obs} , the more likely the observed data did not come from the putative population, so the p-value is $p\text{-value} = P(D \geq d_{\text{obs}})$. The p-value is usually evaluated by the mean of any statistical software and it is obtained by simulations since, under H_0 , the sampling distribution of D does not depend from the specified distribution $F_0(x)$, then a uniform distribution can be employed to evaluate the p-value.

It is worth to observe that it is always possible to apply the One-sample chi-square test described in the previous paragraph to this case, however the Kolmogorov-Smirnov one-sample test treating individual observation separately do not lose information through the binning of categories. Hence it is always preferable to apply Kolmogorov-Smirnov test instead of chi-square test when possible. See Siegel (1956), Ross (2009) for more details.

Finally, we observe that if a goodness of fit test has to be performed with F being normal, then some more powerful tests are available, like Shapiro-Wilk test or Lilliefors test, see Razali and Wah (2011) for discussions and comparisons.

Statistical Tests for the “Two-Samples” Case

Since a paired two sample design can be reduced to a one-sample design considering $\{W_i = (X_i - Y_i)\}_{i=1, \dots, n}$, in this section we only present those tests which are specific for the two independent samples situation, schematically represented in [Fig. 1\(B2\)](#)

Mann-Whitney test

This test allows making inference on the medians of two independent populations.

Assumes we have two sets of data $X_1, \dots, X_n$ and $Y_1, \dots, Y_m$ sampled from two unknown continuous populations with cumulative distribution functions F and G , then this test serves to test $H_0: F=G$ vs $H_1: F \neq G$. Alternatively, if we know that the two populations have the same distribution shape, then this test serves to test the hypothesis that the two distribution have the same median, see [Krzywinski and Altman \(2014a\)](#).

As a first step combine the data from the two samples and sort these $n + m$ values. The value of the U-statistics is given by the number of times that a data from the first population (X) precedes a data from the second population (Y) in the ranking. The sampling distribution of U under H_0 is known and any statistical software can determine the p-value, i.e. the probability associated with the occurrence under H_0 of any U as extreme as the observed value. This test is also known as the Wilcoxon test or the rank sum test and it is the most useful alternative to the two-sample (independent) T-test; see [Krzywinski and Altman \(2014a\)](#) for a detailed comparison between two sample T-test and Mann-Whitney test.

Chi-square test of independence

This test allows making inference on the independence/association of two traits in the paired two-sample experimental design of [Fig. 1\(B1\)](#), where each subject/data of the sample is categorized according to two type of categories/traits. Still, this test allows making inference on two categorical variables in the two independent samples experimental design of [Fig. 1\(B2\)](#), where each data of each of the two samples is categorized according to one type of category/trait.

More formally, suppose we have a sample in which each data can be classified according to two criteria or according to two characteristics, indicated by X and Y , respectively. Suppose that the characteristic X can assume r different values and that the characteristic Y can assume s different values. Denote p_{ij} the probability that a random element from the population takes the value i for the characteristic X and the value j for the characteristic Y .

Let n be the total number of measured subjects/data, evaluate the value of the two characteristics for each element of it, then it is possible to define a contingency table for better representing it. In the contingency table with r rows and s columns, in position ij will be the number of sample elements that simultaneously have the characteristic $X=i$ and the characteristic $Y=j$, denote it O_{ij} . On the margin of the table the observed absolute frequencies for each of the two characteristic will be obtained, denote it np_i for $i=1, \dots, r$ and nq_j for $j=1, \dots, s$. Then, it is possible to test the independency hypothesis $H_0: p_{ij} = p_i q_j \forall i=1, \dots, r \ j=1, \dots, s$ vs $H_1: p_{ij} \neq p_i q_j$ for same i and j . The test statistics results to be:

$$\chi^2 = \sum_{i=1}^r \sum_{j=1}^s \frac{(O_{ij} - E_{ij})^2}{E_{ij}}$$

where O_{ij} is the observed number of cases categorized in i -th row and j -th column and $E_{ij} = np_i q_j$ is the expected number of cases under H_0 to be categorized in the i -th row and j -th column. Under the null hypothesis, the test statistics is distributed like a chi-square with $(r-1)(s-1)$ degree of freedom, then the p-value results to be $P(\chi_{(r-1)(s-1)}^2 \geq t_{obs})$. See [Siegel \(1956\)](#), [Ross \(2009\)](#) for more details.

Finally, let us note that in case $r=s=2$, the same test can be exactly performed using the Fisher-Irwin test which tests the null hypothesis that the probability of being in one or the other of two categories does not depend from belonging to one or the other of the two groups.

Two-sample Kolmogorov-Smirnov test

This test allows making inference on the distributions of two continuous distributions. It tests whether two independent samples have been drawn from the same population (or population with the same distribution). The two populations can have any kind of difference: in location (central tendency), in dispersion, in skewness, etc. Like the Kolmogorov-Smirnov one-sample test, this two-sample test is concerned with the agreement between two cumulative distributions. Specifically, if $F_e(x) = \frac{1}{n} \sum_{i=1}^n \text{Ind}(X_i \leq x)$ is the empirical cumulative distribution function of the first sample and $G_e(x) = \frac{1}{m} \sum_{i=1}^m \text{Ind}(Y_i \leq x)$ is the empirical cumulative distribution function of the second sample, the test statistic is the maximum deviation between them, $D = \max_{-\infty < x < +\infty} |F_e(x) - G_e(x)|$. Under the null hypothesis, the sampling distribution of the test statistics can be obtained, evaluation of the p-value being demanded to specific statistical toolbox. See [Siegel \(1956\)](#) for more details and examples.

Statistical Tests for K Samples

The chi-square test and the median test for k independent samples are the same as the ones for two independent samples, for that reason we demand to the literature for appropriate extension, see for example ([Siegel, 1956](#)). In this section, we present the Kruskal-Wallis one-way analysis of variance by rank, which is the nonparametric counterpart of the one-way ANOVA model presented in Section Statistical Tests for k Samples.

Kruskal-Wallis one-way ANOVA

This non-parametric test allows making inference on the median of more than two populations. Assume we have collected k independent samples each of size n_j , $j = 1, \dots, k$, the Kruskal-Wallis one-way ANOVA tests the hypothesis that the samples come from the same continuous population, or more generally it tests the hypothesis that the k populations have the same median under the assumptions they share the same shape distribution.

The rationale of the method consists of ranking the pooled data from all the k samples and replacing data by their rank. When this has been done, the sum of the ranks in each sample is found and the test determines whether these sums of ranks are so disparate that they are not likely to have come from samples drawn from the same population. More specifically, if $R_j = \sum_{i=1}^{n_j} \text{rank}(X_{ij})$ is the sum of ranks in j th sample and $n = \sum_{j=1}^k n_j$ is the total number of data available into the k samples, then the test statistics is defined by

$$H = \frac{12}{n(n+1)} \sum_{j=1}^k \frac{R_j^2}{n_j} - 3(n+1)$$

Under the null hypothesis, the distribution of the test statistics can be exactly evaluated (in small sample situation) or well approximated by a chi-square with $k - 1$ degree of freedom (in large sample situation); in any case evaluation of the p-value is demanded to specific statistical toolbox. See [Kruskal and Wallis \(1952\)](#), [Siegel \(1956\)](#) for more details and examples.

Finally, let us observe that it is possible to specialize this test to the case of repeated measures or k matched samples, i.e., when the number of observations in each of the k groups are the same. This is known as the Friedman test, see [Siegel \(1956\)](#) for details and examples.

Closing Remarks

This article presents some of the most well-known statistical tests available in literature. For easy of usage, all the tests presented have been summarized in [Table 1](#) along with classical built in functions of Matlab and R. However, the list is not exhaustive and many other functions and statistical tests are available. The most important message is that before applying an hypothesis testing procedure, it is always a good practice to revisit the mathematical assumptions required and look for its documentation, which can be found into the instruction manuals of the most common statistical software, see for example [Krijnen Wim \(2009\)](#), [Mathworks \(R2017a\) \(2017\)](#). Finally, it is important to stress that the above mentioned procedures can be applied for testing individual statistical hypotheses. In the case of multiple tests, the multiplicity correction should be properly taken into account. We demand [Abramovich and Ritov \(2013\)](#) for discussion and methods.

Correlation Analysis

Monica Franzese and Antonella Iuliano, Institute for Applied Mathematics “Mauro Picone”, Napoli, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

In the analysis of health sciences disciplines, usually we are interested to understand the type of relationship that exists between two or more variables. For example, the association between blood pressure and age, height and weight, the concentration of an injected drug and heart rate or the intensity of a stimulus and reaction time. Generally, the strength of relationship between two continuous variables is examined by using a statistical technique called correlation analysis. The concept of correlation was introduced by Sir Francis Galton (1877) in the mid 19th century as the most important contribution to psychological and methodology theory. In 1896, Karl Pearson published his first rigorous treatment of correlation and regression in the *Philosophical Transactions of the Royal Society of London* (Pearson, 1930). Here, he developed the Pearson product-moment correlation coefficient (PPMCC), using an advanced statistical proof based on the Taylor expansion. Today, the term correlation is used in statistics to indicate an association, connection, or any form of relationship, link or correspondence between two or more random variables. In particular, the PPMCC is used to study the linear relationship between two sets of numerical data. The correlation is connected to the concept of covariance that is the natural measure of the joint variability of two random variables. Usually, when we use measures of correlation or covariance from a set of data, we are interested in the degree of the correlation between them. In fact, we cannot prove that one variable causes a change in another if there are no connections between the two variables analyzed. An example is to test if the efficacy of a specific treatment is connected with the dose for the drug in a patient. In this case, a change in the drug variable changes the treatment variable, then the two variables are correlated. Therefore, correlation analysis provides information about the strength and the direction (positive or negative) of a relationship between two continuous variables. No distinction between the explaining variable and the variable to be explained is necessary. On the other hand, regression analysis is used to model or estimate the linear relationship between a response variable and one or more predictor variables (Gaddis and Gaddis, 1990). The simplest regression models involve a single response variable (dependent variable) and a single predictor variable (independent variables). For example, the blood pressure measured at the wrist depends on the dose of some anti-hypertensive drug administered to the patient.

In this work, our discussion is limited to the exploration of the linear (Person correlation) and non-linear relationship (Spearman and Kendall correlations) between two quantitative variables. In particular, we first introduce the concepts of covariance and correlation coefficient, then we discuss how these measures are used in statistics for estimating the goodness-of-fit of linear and non-linear trends and for testing the relationship between two variables. Finally, we explain how the regression analysis is connected to the correlation one. Simulated and real data sets are also presented for the identification and characterization of relationship between two or more quantitative variables.

Measures of Correlation Analysis

In this section, we discuss three correlation measures between two quantitative variables X and Y to determine the degree of association or correlation between them. For example, if we are interested to investigate the association between body mass index and systolic blood pressure, the first step for studying the relationship between these two quantitative variables is to plot a scatter diagram of the data. The points are plotted by assigning values of the independent variable X (body mass index) to the horizontal axis and values of the dependent variable Y (systolic blood pressure) to the vertical axis. The pattern made by the points plotted on the scatter plot usually suggests the nature and strength of the relationship between two variables. For instance, in Fig. 1, the first plot (A) shows that there is no relationship between the two variables X and Y , the second one (B) displays that exist a positive linear relationship between the two variables X and Y , the third one (C) exhibits a negative linear trend between the two variables X and Y . In the last two cases (B and C) the strength of linear relationship is the same but the direction is different, i.e., in (B) the values of Y increase as the values of X increase while in (C) the values of Y decrease as the values of X increase. In addition, the higher the correlation in either direction (positive or negative), the more linear the association between two variables.

Covariance

The covariance quantifies the strength of association between two or more sets of random variables.

Let X and Y be two random variable with the same population size N , we define the covariance as the following expectation value

$$\text{Cov}(X, Y) = E[(X - \mu_x)(Y - \mu_y)] \quad (1)$$

Fig. 1 The plot (A) shows that there is no relationship between the two variables X and Y ; the plot (B) displays that exist a positive linear relationship between the two variables X and Y ; the plot (C) exhibits a negative linear trend between the two variables X and Y .

where $\mu_X = E[X]$ and $\mu_Y = E[Y]$ are the population means of X and Y , respectively. We often denote covariance by σ_{XY} . The variance is a special case of the covariance when the two variables X and Y are identical. In fact, let $\mu = E[X]$ the population mean of X . Then, the covariance is given by

$$\sigma_{XX} = \text{Cov}(X, X) = E[(X - \mu_X)^2] = \text{Var}(X) = \sigma_X^2 \quad (2)$$

By using the linearity property of expectations, formula (1) can be further simplified as follow

$$\begin{aligned}\sigma_{XY} &= \text{Cov}(X, Y) = E[(X - E[X])(Y - E[Y])] \\ &= E[XY] - XE[X] - E[X]Y + E[X]E[Y] \\ &= E[XY] - E[X]E[X] - E[X]E[Y] + E[X]E[Y] = E[XY] - E[X]E[Y]\end{aligned}$$

In other words, the covariance is the population mean of the pairwise cross-product XY minus the cross-product of the means. The formula is given by

$$\sigma_{XY} = \text{Cov}(X, Y) = \mu_{XY} - \mu_X \mu_Y \quad (3)$$

where μ_{XY} is the joint population mean of X and Y . Given a set of paired variables (x, y) with simple size n , the sample covariance is given by

$$\sigma_{xy} = \text{Cov}(x, y) = \frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y}) \quad (4)$$

where

$$\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i \text{ and } \bar{y} = \frac{1}{n} \sum_{j=1}^n y_j$$

are the sample means of variable x and y , respectively. Positive values of covariance, $\sigma_{xy} > 0$, means that the variables are positively related, i.e., the terms $(x_i - \bar{x})(y_i - \bar{y})$ in the sum are more likely to be positive than negative; a negative covariance, $\sigma_{xy} < 0$, indicates that the variables are inversely related, i.e., the terms $(x_i - \bar{x})(y_i - \bar{y})$ in the sum are more likely to be negative than positive. If $\sigma_{xy} = 0$, then the variables x and y are uncorrelated or independent between them. In other words, the sample covariance is positive if y increases with increasing x , negative if y decreases as x increases, and zero if there is no linear tendency for y to change with x . An alternative formula of sample covariance is the following formula (similar to that for a sample variance),

$$\sigma_{xy} = \text{Cov}(x, y) = \frac{n(\overline{xy} - \bar{x}\bar{y})}{n-1} \quad (5)$$

where

$$\overline{xy} = \frac{1}{n} \sum_{i=1}^n x_i y_i$$

is the joint sample mean of x and y . In probability theory, the covariance is a measure of the joint variability of two random variables. In particular, if X and Y are discrete random variables, with joint support S , then the covariance of X and Y is:

$$\text{Cov}(X, Y) = \sum \sum_{(x,y) \in S} (x_i - \mu_x)(y_j - \mu_y) f(x, y) \quad (6)$$

While on the contrary, if X and Y are continuous random variables with supports S_1 and S_2 , respectively, then the covariance of X and Y is:

$$\text{Cov}(X, Y) = \int_{S_1} \int_{S_2} (x_i - \mu_x)(y_j - \mu_y) f(x, y) dx dy \quad (7)$$

In Eqs. (6) and (7), the function $f(x, y)$ is a joint probability distribution, i.e., a probability distribution that gives the probability that X and Y fall in any particular range or discrete set of values specified by the two variables. For instance, we consider two discrete random variable X and Y (bivariate distribution) as illustrated in Table 1. By using the formula (6) the absolute value of covariance, is equal to 0.005. This value indicates a weak degree of association between X and Y .

Correlation Coefficients

In this section, we discuss the most widely used measures of associations between variables: Pearson's product moment correlation coefficient, Spearman's rank correlation coefficient and Kendall's correlation coefficient (Chok, 2010). The correct use of correlation coefficient depends on the type of variables. Pearson's product moment correlation coefficient is used only for continuous variables while the Spearman's and Kendall's correlation coefficients are adopted for either ordinal or continuous variables

Table 1 Joint probability mass function (or bivariate distribution) of two discrete random variables X and Y

$x \backslash y$	1	2	3	$f_X(x)$
1	0.25	0.00	0.25	0.50
2	0.15	0.10	0.25	0.50
$f_Y(y)$	0.40	0.10	0.50	1

Note: The function $f_X(x)$ and $f_Y(y)$ are called marginal distributions. The mean of X and Y are equal to 1.5 and 2, respectively.

(Mukaka, 2012). In addition, the first correlation coefficient is used to quantify linear relationships, the last two correlation coefficients are applied for measuring non-linear (or monotonic) associations.

Pearson's product moment correlation coefficient

Pearson's product moment correlation coefficient r , called also linear correlation coefficient, measures the linear relationship between two continuous variables (Pearson, 1930). Let x and y be the quantitative measures of two random variables on the same sample of n . The formula for computing the sample Pearson's correlation coefficient r is given by

$$r = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2} \sqrt{\sum_{i=1}^n (y_i - \bar{y})^2}} \quad (8)$$

where

$$\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i \text{ and } \bar{y} = \frac{1}{n} \sum_{j=1}^n y_j$$

are the sample means of variable x and y , respectively. In other words, assuming that the sample variances of x and y are positive, i.e., $s_x^2 > 0$ and $s_y^2 > 0$, the linear correlation coefficient r can be written as the ratio of the sample covariance of the two variables to the product of their respective standard deviations s_x and s_y ,

$$r = \frac{\text{Cov}(x, y)}{s_x s_y} \quad (9)$$

Hence, the correlation coefficient is a scaled version of covariance. The sample correlation measurement r ranges between -1 and $+1$. If the linear correlation between x and y is positive (i.e., higher levels of one variable are associated with higher levels of the other) results $r > 0$, while if the linear correlation between x and y is negative (i.e., higher levels of one variable are associated with lower levels of the other) results $r < 0$. The value $r = 0$ indicates absence of any association (positive or negative) between x and y . The sign of the linear correlation coefficient indicates the direction of the association, while the magnitude of the correlation coefficient denotes the strength of the association. If the correlation coefficient is equal to $+1$ the variables have a perfect linear positive correlation. This means that if one variable increases, the second increases proportionally in the same direction. If the correlation coefficient is zero, no relationship exists between the variables. If correlation coefficient is equal to -1 , the variables are perfectly negatively correlated (or inversely correlated) and move in opposition to each other. If one variable increases, the other one decreases proportionally. In addition, when two random variables X and Y are normally distributed, the population Pearson's product moment correlation coefficient is given by

$$\rho = \frac{\text{Cov}(X, Y)}{\sigma_X \sigma_Y} \quad (10)$$

where σ_x and σ_y are the population standard deviations of X and Y , respectively. This coefficient is affected by extreme values and it is therefore not significant when either or both variables are not normally distributed.

Spearman's rank correlation coefficient

Spearman's correlation coefficient evaluates the monotonic relationship between two continuous or ordinal variables (Spearman, 1904). In a monotonic relationship, the variables tend to change together, but not necessarily at a constant rate. Given two random variables x and y , Spearman's rank correlation coefficient computes the correlation between the rank of the two variables. The sample Spearman's rank correlation coefficient r_s is given by the following expression

$$r_s = \frac{\sum_{i=1}^n (x'_i - \bar{x}')(y'_i - \bar{y}')}{\sqrt{\sum_{i=1}^n (x'_i - \bar{x}')^2} \sqrt{\sum_{i=1}^n (y'_i - \bar{y}')^2}} \quad (11)$$

where x' is the rank of x and y' is the rank of y . In other words, it is a rank-based version of the Pearson's correlation coefficient. It ranges from -1 to $+1$. A strong monotonically increasing (or decreasing) association between two variables usually leads to positive (or negative) values of all correlation coefficients simultaneously. Moreover, for weak monotone associations, different correlation coefficients could also be of a different sign. Similar to the Pearson correlation coefficient, Spearman's correlation coefficient is 0 for variables that are correlated in a non-monotonic way. Unlike the Pearson's correlation coefficient, r_s is equal to $+1$ for both linearly and not linearly correlated variables. In addition, there is no requirement of normality for the variables. The corresponding population Spearman's rank correlation coefficient, denoted as ρ_s , describes the strength of a monotonic relationship. This coefficient is computed when one or both variables are skewed or ordinal and it is robust when extreme values are present. An alternative formula used to calculate the Spearman rank correlation is

$$r_s = 1 - \frac{6 \sum_{i=1}^n d_i^2}{n(n^2 - 1)} \quad (12)$$

where d_i is the difference between the ranks of corresponding values x_i and y_i .

Kendall's correlation coefficient

Kendall's correlation coefficient τ is used to measure the monotonic association between two ordinal (not necessarily continuous) variables (Kendall, 1970). The formula to compute τ is

$$\tau = \frac{\sum_{i=1}^n \sum_{j=1}^n \text{sign}(x_i - x_j) \text{sign}(y_i - y_j)}{n(n-1)} \quad (13)$$

where

$$\text{sign}(x_i - x_j) = \begin{cases} 1 & \text{if } \text{sign}(x_i - x_j) > 0 \\ 0 & \text{if } \text{sign}(x_i - x_j) = 0 \\ -1 & \text{if } \text{sign}(x_i - x_j) < 0 \end{cases} \quad \text{and} \quad \text{sign}(y_i - y_j) = \begin{cases} 1 & \text{if } \text{sign}(y_i - y_j) > 0 \\ 0 & \text{if } \text{sign}(y_i - y_j) = 0 \\ -1 & \text{if } \text{sign}(y_i - y_j) < 0 \end{cases}$$

This coefficient measures the discrepancy between the number of concordant and discordant pairs. Any pairs of ranks (x_i, y_i) and (x_j, y_j) are said to be concordant when $x_i < x_j$ and $y_i < y_j$, or $x_i > x_j$ and $y_i > y_j$, or $(x_i - x_j)(y_i - y_j) > 0$. Similarly, any pairs of ranks (x_i, y_i) and (x_j, y_j) are said to be discordant when $x_i < x_j$ and $y_i > y_j$, or $x_i > x_j$ and $y_i < y_j$, or $(x_i - x_j)(y_i - y_j) < 0$. As the two previous correlation coefficients, also τ ranges from -1 to $+1$. It is equal to $+1$ for concordant pairs and -1 for discordant pairs. Both Kendall and Spearman coefficients are formulated as special cases of the Person correlation coefficient.

Confidence Intervals and Testing Hypothesis

Suppose that x and y are two normally distributed variables (mean 0 and standard deviation 1), then the joint distribution is still a normal distribution with probability density

$$f(x) = \frac{1}{2\pi(1-r^2)} \exp \frac{x^2 + 2xy + y^2}{2(1-r^2)}$$

where r is the linear correlation coefficient. This function is called bivariate normal distribution. If the form of the joint distribution is not normal, or if the form is unknown, inferential procedures are invalid, although descriptive measures may be computed. Under the assumption of bivariate normality, given a sample correlation coefficient r , estimated from a sample size of n , we are interested to test if two variables X and Y are linearly correlated, i.e., if $\rho \neq 0$. To estimate ρ (usually unknown), we use the sample correlation statistic r . In particular, we consider the following test statistics

$$r_{obs} = r \sqrt{\frac{n-2}{1-r^2}} \sim T_{(n-2)} \quad (14)$$

which is a statistics distributed as a Student's t variable with $n-2$ degrees of freedom. To test if $\rho \neq 0$, the statistician and biologist Sir Ronald Aylmer Fisher (1921) developed a transformation of r that tends to become normal quickly as the population size n increases. Fisher's z -transformation is a function of r whose sampling distribution of the transformed value is close to normal. It is also called the r to z transformation and it is defined as

$$z = 0.5 \ln \left(\frac{1+r}{1-r} \right) = \text{arctanh}(r) \quad (15)$$

where $\ln$ is the natural logarithm function and arctanh is the inverse hyperbolic tangent function. Then, z is approximately normally distributed with mean

$$\bar{z} = 0.5 \ln \left(\frac{1+\rho}{1-\rho} \right) \quad (16)$$

and standard error

$$\sigma_z = 1/\sqrt{n-3} \quad (17)$$

where n is the sample size. Fisher's z -transformation and its inverses

$$r = \frac{\exp(2z) - 1}{\exp(2z) + 1} = \text{arctanh}(z) \quad (18)$$

can be used to construct a confidence interval for r using standard normal theory and derivations. If the distribution of z is not strictly normal, it tends to be normal rapidly as the sample size increases for any values of ρ . A confidence interval gives an estimated range of r values which is likely to include an unknown population parameter ρ . Generally, it is calculated at a confidence level, usually 95% (i.e., the significance level α is equal to 0.05). If the confidence interval includes 0 we can say that the

Critical regions – Standard normal distribution

Scatter plot

Fig. 3 Scatterplot shows a positive strong linear relationship between x and y variables (on the left of panel); while, it shows a weak association in the other cases; in particular, there is a negative correlation between variables x and z and a positive correlation between variables y and z (on the right of panel).

Note: The dataset contains the following variables: sex (1 = female, 2 = male), height, peak flow (PEFR), and vital capacity (vc) for 44 female and 58 male medical students.

population ρ is not significantly different from zero, at a given level of confidence α . More precisely, using Fisher's z transformation, we calculate the confidence interval at a confidence level α as following:

1. Given the observed correlation r , use Fisher's z transformation to compute the transformed sample correlation z , formula (15), the relative mean $\bar{z}$, formula (16), and standard deviation σ_z , formula (17).
2. Calculate the two-sided confidence limits (lower and upper) for z

$$\left(z - z_{\alpha/2} \sqrt{\frac{1}{n-3}}, z + z_{\alpha/2} \sqrt{\frac{1}{n-3}} \right) \quad (19)$$

where the critical value $z_{\alpha/2}$ depends on the significance level α . The value $\alpha/2$, is the area under the two tails of a standard normal distribution (see Fig. 2).

3. Un-transform the end points of the CI above using the arc tangent transformation, formula (19), in order to derive the confidence limits for the population correlation ρ as (r_{lower}, r_{upper}) .

Confidence intervals are more informative than the simple results of hypothesis tests since they provide a range of possible values for the unknown parameter.

In order to perform hypothesis testing for the population correlation coefficient ρ , we first formulate the null and alternative hypothesis as follow

$$H_0 : \rho = 0 \text{ (X and Y are uncorrelated)} \text{ versus } H_1 : \rho \neq 0 \text{ (X and Y are correlated)}.$$

Then, we use the computed test statistic r_{obs} , formula (14), to find the relative p -value and to make a decision. If the p -value is smaller than the significance level α , then we reject the null hypothesis H_0 and accept the alternative H_1 . In this case, we conclude that exists a linear relationship in the population between the two variables at the level α . If the p -value is larger than the significance level α , we accept the null hypothesis H_0 . In this case, we deduce that there is no linear relationship in the population between the two variables at the level α . Typically, the significant level α is equal to 0.05 or 0.01. This approach is called p -value approach. An alternative method to make a decision is the critical value approach. We find the critical value $t_{\alpha/2, n}$ using the Student's t distribution or t -table (where α is the significance level and n is the degree of freedom) and compare it to the observed r . If the test statistic is more extreme than the critical value, then the null hypothesis is rejected in favor of the alternative hypothesis. If the test statistic is not as extreme as the critical value, then the null hypothesis is not rejected. In other words, we reject the null hypothesis H_0 at the level α if $r_{obs} \leq t_{\alpha/2, n-2}$ and $r_{obs} \geq t_{\alpha/2, n-2}$. Vice versa, we accept the null hypothesis H_0 at the level α if $-t_{\alpha/2, n-2} \leq r_{obs} \leq t_{\alpha/2, n-2}$. For instance, see Fig. 2.

Note that the Fisher z -transformation and the hypothesis test explains above are mainly associated with the Person correlation coefficient for bivariate normal observations, but similar consideration can also be applied to Spearman (Bonett and Wright, 2000; Zar, 2014) and Kendall (Kendall, 1970) correlation coefficients in more general cases.

Fig. 4 Scatterplot between the peak expiratory flow rate (PEFR) and the height of medical students (male and female).

Correlation and Regression

Regression analysis is used to model the relationship between a response variable (dependent variable) and one or more predictor variables (independent variables). Denoting by y the dependent variable and by x the independent variable, the simple linear correlation can be represented using the least squares regression line

$$y = a + bx + e \quad (20)$$

where a is the point where the line crosses the vertical axis y , and b shows the amount by which y changes for each unit change in x . We refer to a as the y -intercept and b as the slope of the line (or regression coefficient). The value e is the residual error. Letting $\hat{y} = \hat{a} + x\hat{b}$ be the value of y predicted by the model, then the residual error is the deviation between observed and the predicted values of the outcome y , i.e., $e = y - \hat{y}$. The aim of linear regression analysis is to estimate the model parameters a and b , in order to give the best fit for the joint distribution of x and y . The mathematical method of least-squares linear regression provides the best-fit solutions. Without making any assumptions about the true joint distribution of x and y , the least-squares linear regression minimizes the average value of the squared deviations of the observed y from the values predicted by the regression line $\hat{y}$. That is, the least-squares solution yields the values of a and b that minimize the mean squared residual, i.e., $e^2 = (y - \hat{y})^2$. The residual is the vertical distances of the data points. The least-squares regression line equation is obtained from sample data by simple arithmetic calculations. In particular, the estimations of a and b that

Fig. 6 Scatterplot between the height and the estimated vital capacity of female medical students.

minimizes the mean squared residual $e^2 = (y - \hat{y})^2$ are given by

$$\hat{b} = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sum_{i=1}^n (x_i - \bar{x})^2}, \hat{a} = \bar{y} - b\bar{x} \quad (21)$$

where x_i and y_i are the corresponding values of each data point (X, Y) , $\bar{x}$ and $\bar{y}$ are the sample means of the X and Y , respectively, and n the sample size. In other words, the estimate of intercept $\hat{a}$ and slope $\hat{b}$ are

$$\hat{b} = \frac{\text{Cov}(x, y)}{\text{Var}(x)}, \hat{a} = \bar{y} - b\bar{x} \quad (22)$$

Thus, the least-squares estimators for the intercept a and slope b of a linear regression are simple functions of the covariances, variances and observed means and define the straight line that minimizes the amount of variation in y explained by a linear regression on x . In addition, the residual errors around the least squares regression are uncorrelated with the predictor variable x . Unlike the correlation analysis, that involves the relationship between two random variables, in the linear regression only the dependent variable is required to be random, while the independent variable is fixed (nonrandom or mathematical). In addition, as for the linear regression, in the correlation analysis we fit a straight line to the data either by minimizing

$$\sum_{i=1}^n (x_i - \hat{x}_i)^2 \text{ or } \sum_{i=1}^n (y_i - \hat{y}_i)^2$$

In other words, we apply a linear regression of X on Y as well as a linear regression of Y on X . These two fitted lines in general are different. Also in this case we use the scatter diagram to plot the regression line. A negative relationship is represented by a falling regression line (regression coefficient $b < 0$), a positive one by a rising regression line ($b > 0$).

Data Analysis and Results

In this section, simulated and clinical data are presented for the study of correlation and regression analysis.

Simulated Data

We generate three random variables x , y , z from three bivariate normal distribution of 30 observations with means equal to zero and standard deviations 2, 3 and 4, respectively. For each pairs of variables, we first plot the scatter diagram in order to visualize the type of correlation that exists among them, and then we compute the covariance and the three correlation coefficients. Fig. 3 shows that the variables x and y have a positive covariance and a positive correlation, while the variables y and z have a negative covariance and a negative correlation. In particular, the Person correlation coefficient $r_{xy} = 0.94$ indicates that there is a strong positive association between the variables x and y , whereas Person correlation coefficient $r_{yz} = 0.03$ shows a weak positive relationship between the variables y and z . These results are confirmed by Spearman correlation coefficients $r_{sxy} = 0.93$ and $r_{syx} = 0.05$ and Kendall correlation coefficients $\tau_{xy} = 0.78$ and $\tau_{yz} = 0.04$. On the contrary, the variables x and z present a negative covariance and a negative correlation. In fact, Person correlation coefficient is $r_{xz} = -0.01$ which indicates a

Table 4 In the table are reported the covariance and the three different correlation coefficients (Pearson, Spearman and Kendall) for the female medical students dataset. The regression coefficients are also shown

		Height	PEFR	Vital capacity
Covariance	Height	34.30	100.16	2.50
	PEFR	100.16	2407.32	9.62

	Vital capacity vs. height	$a = -8.81, b = 0.07$		

weak negative correlation. This result is validated by Spearman correlation coefficient $r_{sz} = -0.02$ and Kendall correlation coefficient $r_{xz} = -0.02$. Finally, we test if these three correlation coefficients are statistically significant. Using parametric assumptions (Pearson, dividing the coefficient by its standard error, giving a value that follow a t -distribution), for the pair (x,y) the confidence interval at level 95% ($\alpha=0.05$) is $(0.88, 0.97)$. In other words, we reject the null hypothesis H_0 . In fact, the p -value $= 1.118e-14$ is statistically significant, since it is less than 0.05. Similar results are obtained when data violate parametric assumptions (Spearman and Kendall). Also in these cases the p -value is statistically significant (p -value $= 5.562e-08$ and p -value $= 1.953e-12$). On the contrary, for the pairs (x,z) and (y,z) , we accept the null hypothesis H_0 for the three type of correlation coefficients (Person, Spearman and Kendall) take into account. In fact, the three tests are not statistically significant (p -value > 0.05) (Table 2).

Clinical Data

The clinical data is downloaded (See Section Relevant Websites). The data is composed by 44 female and 58 male medical students. It contains information about the peak expiratory flow rate (PEFR, measured in litre/min), which is a form of pulmonary function test used to measure how fast a person can exhale, the height of students and the vital capacity (vc), which is the maximum amount of air a person can expel from the lungs after a maximum inhalation (measured in litre). In particular, the vital capacity (vc) is reported only for female students. The scatter plot in Fig. 4 shows a positive correlation between the peak expiratory

Fig. 7 Least squares line between the variables PEFR and height of the medical students (female and male).

flow rate (PEFR) and the height of all students (male and female). This result is confirmed by the computation of covariance and correlation coefficients (Person, Spearman and Kendall) as shown in [Table 3](#). The Person and Spearman correlation coefficients indicate a moderate positive relationship ($r=0.64$ and $r_s=0.67$), while the Kendall correlation coefficient indicates a weak positive relationship ($\tau=0.48$). In particular, for the female group of medical students, [Figs. 5](#) and [6](#) show a positive association for the variables (vc, PEFR) and (height, vc), respectively. Also in this case the positive relationship is validated by the computation of covariance and correlation coefficients (Person, Spearman and Kendall) as shown in [Table 4](#). In particular, the three correlation coefficients indicate a weak positive relationship ($r=0.34$, $r_s=0.33$ and $\tau=0.24$) for the variables (vc, PEFR), while they indicate a strong positive relationship ($r=0.74$, $r_s=0.70$ and $\tau=0.54$) for the variables (height, vc). Finally, the regression analysis is also performed. In [Fig. 7](#), we plot the least-squares line between the dependent variable PEFR and the independent variable height when female and male are considered together. The least-squares equation is $\hat{y} = -461.84 + 5.74\hat{x}$. On the other hand, in [Figs. 8](#) and [9](#), the least-squares line between PEFR and vital capacity (vc) and vital capacity and height are plotted, respectively. The least-squares equations are $\hat{y} = 380.10 + 28.87\hat{x}$ and $\hat{y} = -8.81 + 0.07\hat{x}$.

Software

We use the R statistical software (see Relevant Website section) to elaborate the strength of correlation and to analyze the regression relationship between the variables under investigated in both cases studies. In particular, we apply the common used statistical packages in R.

Fig. 8 Least squares line between the variables PEFR and vital capacity of the female medical students.

Fig. 9 Least squares line between the variables vital capacity and height of the female medical students.

Conclusions

Correlation analysis is an important statistical method for the analysis of medical data. It is used to investigate the relationship between two quantitative continuous variables. In particular, a correlation coefficient measures the strength of the relationship (magnitude) between two variables and the direction of the relationship (sign). We analyzed three different type of correlation coefficient. Pearson correlation coefficient quantifies the strength of a linear relationship between two variables. Spearman and Kendall correlation coefficients are two rank-based (or non-parametric) version of the Pearson coefficient. When two variables are normally distributed we use Pearson coefficient, otherwise, we apply Spearman or Kendall coefficient. Moreover, Spearman coefficient is more robust to outliers than is Pearson coefficient. Finally, since the correlation analysis does not establish if one variable is dependent and the other is independent, we introduce the regression analysis which is another statistical method used to describe a linear relationship between a depend variable (response or outcome) and one or more independent variables (predictors or explanatory variables). Therefore, the correlation analysis can be defined as a double linear regression of X on Y and of Y on X .

Nomenclature

$Y = (Y_1, Y_2, \dots, Y_n)^T$ denotes the $n \times 1$ vector of responses

$\varepsilon = (\varepsilon_1, \varepsilon_2, \dots, \varepsilon_n)^T$ denotes the $n \times 1$ vector of errors/noise

$X = \begin{pmatrix} 1, x_{11}, x_{12}, \dots, x_{1p} \\ 1, x_{21}, x_{22}, \dots, x_{2p} \\ \dots \\ 1, x_{n1}, x_{n2}, \dots, x_{np} \end{pmatrix}$ denotes the $n \times (p+1)$ matrix of regressors (i.e., *design matrix*)

$x_i = (x_{i1}, \dots, x_{ip})^T$ (or $x_i = (1, x_{i1}, \dots, x_{ip})^T$) denotes the $p \times 1$ (or $(p+1) \times 1$) vector of covariates observed on the i th statistical unit

$X_k = (x_{1k}, \dots, x_{nk})^T$ denotes the $n \times 1$ vector of observations for the k th covariate

$\beta = (\beta_0, \beta_1, \dots, \beta_p)^T$ denotes the $(p+1) \times 1$ vector of unknown regression coefficients

$\hat{\beta} = (\hat{\beta}_0, \hat{\beta}_1, \dots, \hat{\beta}_p)^T$ denotes the $(p+1) \times 1$ vector of estimated regression coefficients

$\hat{Y} = (\hat{Y}_1, \hat{Y}_2, \dots, \hat{Y}_n)^T$ denotes the $n \times 1$ vector of responses

$H = X(X^T X)^{-1} X^T$ denotes the $n \times n$ hat-matrix.

$E()$ denotes the Expected value

T_{n-p-1} denotes a Student distribution with $n-p-1$ degree of freedom

$t_{n-p-1, \alpha}$ denotes the $(1-\alpha)$ quantile of a T_{n-p-1} distribution

$\|\beta_i\|_2^2 = \sum_{i=1}^p \beta_i^2$ denotes the l_2 vector norm

$\|\beta_1\|_1 = \sum_{i=1}^p |\beta_i|$ denotes the l_1 vector norm

Introduction

Regression analysis is a well-known statistical learning technique useful to infer the relationship between a *dependent variable* Y and p *independent variables* $X = [X_1 | \dots | X_p]$. The dependent variable Y is also known as *response variable* or *outcome*, and the variables X_k ($k=1, \dots, p$) as *predictors*, *explanatory variables*, or *covariates*. More precisely, regression analysis aims to estimate the mathematical relation $f()$ for explaining Y in terms of X as, $Y=f(X)$, using the observations $(x_i, Y_i), i=1, \dots, n$, collected on n observed *statistical units*. If Y describes a univariate random variable the regression is said to be *univariate regression*, otherwise it is referred as *multivariate regression*. If Y depends on only one variable x (i.e., $p=1$), the regression is said *simple*, otherwise (i.e., $p>1$), the regression is said *multiple*, see (Abramovich and Ritov, 2013; Casella and Berger, 2001; Faraway, 2004; Fahrmeir et al., 2013; Jobson, 1991; Rao, 2002; Sen and Srivastava, 1990).

For the sake of brevity, in this chapter we limit our attention to *univariate regression* (simple and multiple), so that $Y = (Y_1, Y_2, \dots, Y_n)^T$ represents the vector of observed outcomes, and $X = \begin{pmatrix} x_1^T \\ \dots \\ x_n^T \end{pmatrix}$ represents the *design matrix* of observed covariates, where $x_i = (x_{i1}, \dots, x_{ip})^T$ (or $x_i = (1, x_{i1}, \dots, x_{ip})^T$). In this setting $X = [X_1 | \dots | X_p]$ is a p -dimensional variable ($p \geq 1$).

Regression analysis techniques can be organized into two main categories: non-parametric and parametric. The first category contains those techniques that do not assume a particular form for $f()$; while the second category includes those techniques based on the assumption of knowing the relationship $f()$ up to a fixed number of parameters β that need to be estimated from the observed data. When the relation between the explanatory variables, X , and the parameters, β , is linear, the model is known as *Linear Regression Model*.

The Linear Regression Model is one of the oldest and more studied topics in statistics and is the type of regression most used in applications. For example, regression analysis can be used for investigating how a certain phenotype (e.g., blood pressure) depends on a series of clinical parameters (e.g., cholesterol level, age, diet, and others) or how gene expression depends on a set of transcription factors that can up/down regulate the transcriptional level, and so on. Despite the fact that linear models are simple and easy to handle mathematically, they often provide an adequate and interpretable estimate of the relationship between X and Y . Technically speaking, the linear regression model assumes the response Y to be a continuous variable defined on the real scale and each observed data is modeled as

$$Y_i = \beta_0 + \beta_1 x_{i1} + \dots + \beta_p x_{ip} + \varepsilon_i = x_i^T \beta + \varepsilon_i \quad i = 1, \dots, n$$

where $\beta = (\beta_0, \beta_1, \dots, \beta_p)^T$ is a vector of unknown parameters called *regression coefficients* and ε represents the *errors* or *noise term* that accounts for the randomness of the measured data or the residual variability not explained by X . The regression coefficients β can be estimated by fitting the observed data using the least squares approach. Under the Gauss-Markov conditions (i.e., the ε_i are assumed to be independent and identically distributed random variables, with zero mean and finite variance σ^2), the ordinary least squares estimates $\hat{\beta}$ are guaranteed to provide the *best linear unbiased estimator* (BLUE). Moreover, under the further assumptions that $\varepsilon \sim N(0, \sigma^2 I_n)$, $\hat{\beta}$ allows statistical inference to be carried out on the model, as described later. The validity of both the

Gauss-Markov conditions and the normal distribution of the error term are known as “white noise” conditions. In this context, linear regression model is also known as the regression of the “mean”, since it models the conditional expectation of Y given X , as follows $\hat{Y} = E(Y|X) = X^T \hat{\beta}$, where $E(Y|X)$ denotes the conditional expected value of Y for fixed values of the regressors X .

The linear regression model not only allows estimating the regression coefficients β as $\hat{\beta}$ (and hence quantifying the strength of the relationship between Y and each of the p explanatory variables when the remaining $p-1$ are fixed), but also selecting those variables that have no relationship with Y (when the remaining ones are fixed), as well as identifying which subsets of explanatory variables have to be considered in order to explain sufficiently well the response Y . These tasks can be carried out by testing the significance of each individual regression coefficient when the others are fixed, by removing the coefficients that are not significant and re-fitting the linear model and/or by using model selection approaches. Moreover, linear regression model can be also used for prediction. For this purpose, given the estimated values, $\hat{\beta}$, it is possible to predict the response, $\hat{Y}_0 = x_0^T \hat{\beta}$, corresponding to any novel value x_0 and to estimate the uncertainty of such prediction. The uncertainty depends on the type of prediction one wants to make. In fact, it is possible to compute two types of confidence intervals: the one for the expectation of a predicted value at a given point x_0 , and the one for a future generic observation at a given point x_0 .

As the number, p , of explanatory variables increases, the least squares approach suffers from a series of problems, such as lack of prediction accuracy and difficulty of interpretation. To address these problems, it is desirable to have a model with only a small number of “important” variables, which is able to provide a good explanation of the outcome and good generalization at the price of sacrificing some details. Model selection consists in identifying which subsets of explanatory variables have to be “selected” to sufficiently explain the response Y making a compromise referred as the *bias-variance trade-off*. This is equivalent to choosing between competing linear regression models (i.e., with different combinations of variables). On the one hand, one has to consider that including too few variables leads to so-called “underfit” of the data, characterized by poor prediction performance with high bias and low variance. On the other hand, selecting too many variables leads to so-called “overfit” of the data, characterized by poor prediction performance with low bias and high variance. Stepwise linear regression is an attempt to address this problem (Miller et al., 2002; Sen and Srivastava, 1990) constituting a specific example of subset regression analysis. Although model selection can be used in classical regression context, it is one of the most effective tool in high dimensional data analysis.

Classical regression deal with the case $n \geq p$ where n denotes the number of independent observations (i.e., the sample size) and p the number of variables. Nowadays, in many applications especially in biomedical science, high-throughput assays are capable of measuring from thousands to hundreds of thousands of variables on a single statistical unit. Therefore, one has often to deal with the case $p \gg n$. In such a case, ordinary least squares cannot be applied, and other types of approaches (for example, including the use of a penalization function) such as Ridge regression, Lasso or Elastic net regression (Hastie et al., 2009; James et al., 2013; Tibshirani, 1996, 2011) have to be used for estimating the regression coefficients. In particular, Lasso is very effective since it also performs also variable selection and has opened the new framework of high-dimensional regression (Bühlmann and van de Geer, 2011; Hastie et al., 2015). Model selection and high dimensional data analysis are strongly connected, and they might also benefit from dimension reduction techniques such as principal component analysis, or feature selection.

In the classical framework, Y is treated as a random variable, while X are considered fixed, hence, depending on the distribution of Y , different types of regression models can be defined. With X fixed, the assumptions on the distribution of Y are elicited through the distribution of error term $\varepsilon = (\varepsilon_1, \dots, \varepsilon_n)^T$. As above mentioned, classical linear regression requires the error term to satisfy the Gauss-Markov conditions and be normally distributed. However, when the error term is not normally distributed, linear regression might be not appropriate. Generalized linear models (GLM) constitute a generalization of classical linear regression that allows the response variable Y to have an error distribution other than normal (McCullagh and Nelder, 1989). In this way, GLM generalize linear regression by allowing the linear model to be related to the response variable via a *link function*, and by allowing the magnitude of the variance of each measurement to be a function of its predicted value. In this way GLM represent a wide framework that includes linear regression, logistic regression, Poisson regression, multinomial regression, etc. In this framework the regression coefficients can be estimated using the *maximum likelihood* approach, often solved by iteratively reweighted least squares algorithms.

In the following, we briefly summarize the key concepts and definitions related to linear regression, moving from the simple linear model, to the multiple linear model. In particular, we discuss the Gauss-Markov conditions and the properties of the least squares estimate. We discuss the concepts of model selection and also provide suggestions on how to handling outliers and deviation from standard assumptions. Then, we discuss modern forms of regression, such as Ridge regression, Lasso and Elastic Net, which are based on penalization terms and are particularly useful when the dimension of the variable space, p , increases. We conclude by extending the linear regression concepts to the Generalized Linear Models (GLM).

Background/Fundamentals

In the following we first introduce the main concepts and formulae for simple linear regression ($p=1$), then we extend the regression model to the case $p>1$. We note that, when $p=1$, simple linear regression is the “best” straight line through the observed data points, for $p>1$ it represents the “best” hyper-plane across the observed data points. Moreover, while Y has to be a quantitative variable, the X_k can be either quantitative or categorical. However, categorical covariates have to be transformed into a series of dummy variables using indicators.

Simple Linear Regression

As mentioned before, simple linear regression (Altman and Krzywinski, 2015; Casella and Berger, 2001) is a statistical model used to study the relationship $f()$ between two (quantitative) variables x and Y , where Y represents the response variable and x the explanatory variable (i.e., x is one particular X_k), assuming that the mathematical relation can be described by a straight line. In particular, the aim of simple linear regression is estimating the straight line that best fits the observed data, by estimating its coefficients (i.e., the intercept and the slope), quantifying the uncertainty of such estimate, testing the significance of the relationship, and finally using the estimated line to predict the value of Y using the observed values of x . Typically the x variable is treated as fixed, and the aim is estimating the relationship between the mean of Y and x (i.e., $E[Y|x]$ where E denotes the conditional expectation of Y given x).

More formally, to fix the notation and introduce the general concepts, assume we have collected n observations (x_i, Y_i) , $i = 1, \dots, n$. A simple linear regression model can be written as

$$Y_i = \beta_0 + \beta_1 x_i + \varepsilon_i \quad i = 1, \dots, n$$

where the ε_i are independent and identically distributed random variables (with zero mean and finite variance σ^2) and $\beta_0 + \beta_1 x$ represents a straight line, β_0 being the intercept and β_1 the slope. In particular, when $\beta_1 > 0$, x and Y vary together; when $\beta_1 < 0$ then x and Y vary in opposite directions.

Let $\mathbf{Y} = (Y_1, Y_2, \dots, Y_n)^T$ and $\boldsymbol{\varepsilon} = (\varepsilon_1, \varepsilon_2, \dots, \varepsilon_n)^T$ denote the vectors of the observed outcomes and the noise, respectively, $\mathbf{X} = \begin{pmatrix} 1 & 1 & \dots & 1 \\ x_1 & x_2 & \dots & x_n \end{pmatrix}^T = \begin{pmatrix} 1_n \\ \mathbf{x} \end{pmatrix}^T$, the matrix of regressors (usually called the *design matrix*), and $\boldsymbol{\beta} = (\beta_0, \beta_1)^T$, the vector of unknown coefficients, then the regression problem can be rewritten in matrix form as,

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$$

The aim is estimating the coefficients $\boldsymbol{\beta} = (\beta_0, \beta_1)^T$ that provide a “best” fit for the observed data. This “best” fit is often achieved by using the *ordinary least-squares* approach, i.e., by finding the coefficients that minimizes the sum of the squared residuals, or in mathematical terms by solving the following problem

$$\underset{\beta_0, \beta_1}{\operatorname{argmin}} \sum_{i=1}^n e_i^2 = \underset{\beta_0, \beta_1}{\operatorname{argmin}} \sum_{i=1}^n (Y_i - \beta_0 - \beta_1 x_i)^2$$

After straightforward calculations, it is possible to prove that

$$\hat{\beta}_1 = \frac{\sum_{i=1}^n (x_i - \bar{x})(Y_i - \bar{Y})}{\sum_{i=1}^n (x_i - \bar{x})^2}$$

$$\hat{\beta}_0 = \bar{Y} - \hat{\beta}_1 \bar{x}$$

where $\bar{Y} = \frac{\sum_{i=1}^n Y_i}{n}$ and $\bar{x} = \frac{\sum_{i=1}^n x_i}{n}$ denote the sample mean of Y and x , respectively. The estimate of $\hat{\beta}_1$ can be rewritten as

$$\hat{\beta}_1 = \frac{s_{xY}}{s_{xx}} = r_{xY} \frac{s_{YY}}{s_{xx}}$$

where s_{xx} and s_{YY} denote the sample variance of x and Y , respectively; r_{xY} and s_{xY} denote the sample correlation and sample covariance coefficient between x and Y , respectively.

Given the estimated parameters $\hat{\beta}_0, \hat{\beta}_1$, it is possible to estimate the response, $\hat{Y}_i$, as

$$\hat{Y}_i = \hat{\beta}_0 + \hat{\beta}_1 x_i \quad i = 1, \dots, n$$

The least squares approach provides a good estimate of the unknown parameters if the so-called Gauss-Markov conditions are satisfied (i.e., i. $E(\varepsilon_i) = 0$, $\forall i = 1, \dots, n$, ii. $E(\varepsilon_i^2) = \sigma^2$, $\forall i = 1, \dots, n$ and iii. $E(\varepsilon_i \varepsilon_j) = 0$, $\forall i \neq j$, where $E()$ denotes the expected value). In particular, according to the Gauss-Markov theorem, if such conditions are satisfied, the least squares approach provides the *best linear unbiased estimator* (BLUE) of the parameters, i.e., the estimate with the lowest variance compared to all linear unbiased estimators. Furthermore, if we also assume that $\varepsilon_i \sim N(0, \sigma^2)$ then, the least squares solution provides the best estimator among all unbiased estimators, and also the maximum likelihood estimator. Additionally, under such assumptions (“white noise” assumptions) it is possible to prove that

$$\frac{\beta_i - \hat{\beta}_i}{s_{\hat{\beta}_i}} \sim T_{n-2}, \quad i = 0, 1$$

where $s_{\hat{\beta}_i} = \sqrt{\frac{1}{n-2} \sum_{i=1}^n \frac{e_i^2}{(x_i - \bar{x})^2}}$ is the *standard error* of the estimator $\hat{\beta}_i$, and T_{n-2} denotes the Student T-distribution with $n-2$ degree of freedom. On the basis of this result, the $(1-\alpha)$ % *percent confidence interval* for the coefficient, β_i , is given by

$$\beta_i = \left[\hat{\beta}_i - s_{\hat{\beta}_i} t_{n-2, \frac{\alpha}{2}}, \hat{\beta}_i + s_{\hat{\beta}_i} t_{n-2, \frac{\alpha}{2}} \right], \quad i = 0, 1$$

where $t_{n-2, \frac{\alpha}{2}}$ denotes the $(1-\alpha/2)$ quantile of T_{n-2} .

Moreover, the significance of each coefficient can be evaluated by testing the null hypothesis $H_{0,i} : \beta_i = 0$ versus the alternative $H_{1,i} : \beta_i \neq 0$. To perform such test, it is possible to use the following test statistics $\frac{\hat{\beta}_i}{s_{\hat{\beta}_i}} \sim T_{n-2}$, $i = 0, 1$.

Finally, the *coefficient of determination*, R^2 , is commonly used to evaluate the *goodness of fit* within a simple linear regression model. It is defined as follows

$$R^2 = \frac{\sum_{i=1}^n (\hat{Y}_i - \bar{Y})^2}{\sum_{i=1}^n (Y_i - \bar{Y})^2} = 1 - \frac{\sum_{i=1}^n (Y_i - \hat{Y}_i)^2}{\sum_{i=1}^n (Y_i - \bar{Y})^2}$$

We have that $R^2 \in [0, 1]$, where 0 (or a value close to 0) indicates that the model explains none (or little) of the variability of the response data around its mean; 1 (or a value close to 1) indicates that the model explains all (or most) of the variability of the response data around its mean. Moreover, if $R^2 = 1$ the observed data are distributed on the regression line (perfect fitting). Note that $R^2 = r^2$ were, r , denotes the Pearson correlation coefficient that can be computed as

$$r = \frac{n \sum_{i=1}^n x_i y_i - \sum_{i=1}^n x_i \sum_{i=1}^n y_i}{\sqrt{n \sum_{i=1}^n x_i^2 - (\sum_{i=1}^n x_i)^2} \sqrt{n \sum_{i=1}^n y_i^2 - (\sum_{i=1}^n y_i)^2}}$$

Ordinary least squares regression is the most common approach to defining the “best” straight line that fit the data. However, there are other regression methods that can be used in place of ordinary least squares, such as the least absolute deviations (i.e., the line that minimizes the sum of the absolute values of the residuals)

$$\operatorname{argmin}_{\beta_0, \beta_1} \sum_{i=1}^n |e_i| = \operatorname{argmin}_{\beta_0, \beta_1} \sum_{i=1}^n |Y_i - \beta_0 - \beta_1 x_i|$$

see (Sen and Srivastava, 1990) for a more detailed discussion.

Multiple Linear Regression

Multiple linear regression generalizes the above mentioned concepts and formulae to the case where more predictors are used (Abramovich and Ritov, 2013; Casella and Berger, 2001; Faraway, 2004; Fahrmeir *et al.*, 2013; Jobson, 1991; Krzywinski and Altman, 2015; Rao, 2002; Sen and Srivastava, 1990).

Let $\mathbf{Y} = (Y_1, Y_2, \dots, Y_n)^T$ and $\boldsymbol{\varepsilon} = (\varepsilon_1, \varepsilon_2, \dots, \varepsilon_n)^T$ denote the vectors of the observed outcomes and the noise, respectively,

$$\mathbf{X} = \begin{pmatrix} 1, x_{11}, x_{12}, \dots, x_{1p} \\ 1, x_{21}, x_{22}, \dots, x_{2p} \\ \dots \\ \dots \\ 1, x_{n1}, x_{n2}, \dots, x_{np} \end{pmatrix}$$

is the *design matrix*, and $\boldsymbol{\beta} = (\beta_0, \beta_1, \dots, \beta_p)^T$ is the vector of unknown coefficients, then the regression problem can be rewritten in matrix form as,

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$$

The least squares estimate of $\boldsymbol{\beta}$ can be obtaining by solving the following problem

$$\operatorname{argmin}_{\beta_0, \beta_1, \dots, \beta_p} \sum_{i=1}^n e_i^2 = \operatorname{argmin}_{\beta_0, \beta_1, \dots, \beta_p} \sum_{i=1}^n (Y_i - \beta_0 - \beta_1 x_{i1} - \beta_2 x_{i2} \dots - \beta_p x_{ip})^2 = \operatorname{argmin}_{\boldsymbol{\beta}} (\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})^T (\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})$$

It can be proved that if $\mathbf{X}^T \mathbf{X}$ is a non-singular $p \times p$ matrix, and $(\mathbf{X}^T \mathbf{X})^{-1}$ denotes its inverse matrix, then there exists a unique solution given by

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{Y}$$

If $\mathbf{X}^T \mathbf{X}$ is singular, the solution is not unique, but it can be still computed in terms of the pseudo-inverse matrix $(\mathbf{X}^T \mathbf{X})^+$ as follows

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}^T \mathbf{X})^+ \mathbf{X}^T \mathbf{Y}$$

Once the estimate $\hat{\boldsymbol{\beta}}$ has been computed, it is possible to estimate $\hat{\mathbf{Y}}$ as

$$\hat{\mathbf{Y}} = \mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{X}(\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{Y} = \mathbf{H}\mathbf{Y}$$

where $\mathbf{H} = \mathbf{X}(\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T$ is called the *hat-matrix* or *projection matrix*. From a geometrical point of view, in a n -dimensional Euclidean space, $\hat{\mathbf{Y}}$ can be seen as the orthogonal projection of $\mathbf{Y}$ in the subspace generated by the columns of $\mathbf{X}$, and the vector of *residuals*, defined as $\mathbf{e} = \mathbf{Y} - \hat{\mathbf{Y}}$, is orthogonal to the subspace generated by the columns of $\mathbf{X}$.

Moreover, under the assumption that the Gauss-Markov conditions hold, the least squares estimate, $\hat{\boldsymbol{\beta}}$, is the BLUE, and an unbiased estimate of the variance is given by

$$\hat{\sigma}^2 = \frac{1}{n - p - 1} \sum_{i=1}^n (Y_i - \hat{Y}_i)^2$$

Analogously to simple linear regression, the coefficient of determination, $R^2 = \frac{\sum_{i=1}^n (\hat{Y}_i - \bar{Y})^2}{\sum_{i=1}^n (Y_i - \bar{Y})^2}$, can be used to evaluate the goodness of fit ($R^2 \in [0, 1]$). However, the value of R^2 increases as p increases. Therefore, it is not a useful measure for selecting parsimonious models. The *adjusted* R^2 , R_a^2 , is defined as

$$R_a^2 = 1 - \frac{\sum_{i=1}^n \frac{(Y_i - \hat{Y}_i)^2}{(n-p-1)}}{\sum_{i=1}^n \frac{(Y_i - \bar{Y})^2}{(n-1)}} = 1 - \frac{SSE/(n-p-1)}{SST/(n-1)}$$

which adjusts for the number of explanatory variables in the model.

Overall we have the following partition of the errors: $SST = SSR + SSE$ where $SST = \sum_{i=1}^n (Y_i - \bar{Y})^2$ denotes the total sum of squares, $SSR = \sum_{i=1}^n (\bar{Y}_i - \hat{Y}_i)^2$, the sum of squares explained by the regression, and $SSE = \sum_{i=1}^n (Y_i - \hat{Y}_i)^2$, the residual sum of squares due to the error term.

Gauss-Markov Conditions and Diagnostics

Linear regression and the ordinary least squares approach are based on the so-called Gauss-Markov conditions

- 1) $E(\varepsilon_i) = 0$ (*Zero-mean error*)
- 2) $E(\varepsilon_i^2) = \sigma^2 \forall i = 1, \dots, n$ (*Homoscedastic error*)
- 3) $E(\varepsilon_i \varepsilon_j) = 0 \forall i \neq j$ (*Independent errors*)

that guarantee $\hat{Y} = X\hat{\beta} = X(X^T X)^{-1} X^T Y$ is the *best linear unbiased estimator* (BLUE) of the coefficients (Gauss-Markov theorem, Jobson, 1991; Sen and Srivastava, 1990).

When using linear regression functions it is important to verify the validity of such assumptions using so-called residual plots (Altman and Krzywinski, 2016b). Moreover, in order to perform inference on the significance of the regression coefficients and prediction of future outcomes, it is necessary that $\varepsilon \sim N(0, \sigma^2 I_n)$ also holds. This condition can be verified using the Shapiro-Wilk test or the Lilliefors test, see (Razali and Wah, 2011) or the Chapter *Statistical Inference Techniques* in this volume.

Tests of significance and confidence regions

One of the most important aspects of regression is that it is possible to make inference on the estimated model, this means it is possible to test the significance of each coefficients (i.e., $H_0 : \beta_j = 0$ vs $H_1 : \beta_j \neq 0$), assuming the other are fixed, and to build confidence intervals. In particular, under the “white noise” assumptions, it is possible to prove that

$$\hat{\beta} \sim N(\beta, (X^T X)^{-1} \sigma^2)$$

and

$$(n-p-1)\hat{\sigma}^2 \sim \sigma^2 \chi_{n-p-1}^2$$

where χ_{n-p-1}^2 denotes a chi-squared distribution with $n-p-1$ degree of freedom. Moreover the two estimates are statistically independent. Hence, it is possible to show that (under the null hypothesis)

$$\frac{\hat{\beta}_j - \beta_j}{s_{\hat{\beta}_j}} \sim T_{n-p-1}$$

is a Student distribution T_{n-p-1} with $n-p-1$ degree of freedom. These results can be used to decide whether β_j are significant (where, $s_{\hat{\beta}_j}$ denotes the standard deviation of the estimated coefficients, i.e., $s_{\hat{\beta}_j} = \sqrt{\text{var}(\hat{\beta}_j)}$).

Moreover the $100(1-\alpha)\%$ confidence interval for the regression coefficient, $\hat{\beta}_j$, is given by $\hat{\beta}_j \pm s_{\hat{\beta}_j} t_{n-p-1, \frac{\alpha}{2}}$, where $t_{n-p-1, \frac{\alpha}{2}}$ is the corresponding quantile of the T distribution with $n-p-1$ degree of freedom. More details about significance testing, including the case of contrasts between coefficients, can be found in Sen and Srivastava (1990), Jobson (1991).

Inference for the model

The overall *goodness of fit* of the model can be measured testing the null assumption $H_0 : \beta_1 = \beta_2 = \dots = \beta_p = 0$ using the F-test

$$F = \frac{SSR/p}{SSE/(n-p-1)}$$

which has a Fisher distribution with p and $n-p-1$ degree of freedom.

Confidence interval (CI) for the expectation of a predicted value at x_0

Let $x_0 = (x_{00}, x_{01}, \dots, x_{0p})$ be a novel observation of the independent variables X , and let y_0 be the unobserved response. Then, the predicted response is $\hat{y}_0 = x_0^T \hat{\beta}$ and the $100(1-\alpha)\%$ confidence interval of its expected value is

$$\hat{y}_0 \pm t_{n-p-1, \alpha} \hat{\sigma}^2 \left[x_0^T (X^T X)^{-1} x_0 \right]$$

CI for a future observation x_0

Under the same settings, the $100(1-\alpha)\%$ confidence interval for the predicted response is

$$\hat{y}_0 \pm t_{n-p-1, \alpha} \hat{\sigma}^2 \left[1 + \mathbf{x}_0^T (X^T X)^{-1} \mathbf{x}_0 \right]$$

Subset Linear Regression

In many cases, the number of observed variables, X , is large and one seeks for a regression model with a smaller number of “important” variables in order to gain explicative power and to address the so-called variance-bias trade off. In these cases a small subset of the original variables must be selected, and the regression hyper-plane fit using the subset. In principle, one can choose a goodness criterion and compare all potential models using such criteria. However if p denotes the number of observed variables, there will be 2^p potential models to compare. Therefore, for large p such an approach becomes unfeasible. Stepwise linear regression methods allow one to select a subset of variables by adding or removing one variable at a time and re-fitting the model. In this way, it is possible to choose a “good” model by fitting only a limited number of potential models. *Mallows' C_p* , *AIC* (Akaike's information criterion), and *BIC* (Bayesian information criterion) are widely used for choosing “good” models. More details can be found in [Sen and Srivastava \(1990\)](#), [Jobson \(1991\)](#), [Miller \(2002\)](#), [Lever et al., \(2016\)](#).

Regression Analysis in Practice

How to Report the Results of a Linear Regression Analysis and Diagnostic Plots

After fitting a linear regression model one has to report the estimates of the regression coefficients and their significance. However, this is not sufficient for evaluating the overall significance of the fit. The R^2 (or the R_a^2) are typical measures of quality that should be reported, as well as the overall significance, F , of the regression model. Moreover, results have to be accompanied by a series of diagnostic plots and statistics on residuals that can be used to validate the Gauss-Markov conditions. Such analyses include normal-quantile residual and fitted-residual plots. The key aspect to keep in mind is that when fitting a linear regression model by using any software, the result will provide the “best” hyper-plane or the “best” straight line, regardless of the fact that the model is inappropriate. For example, in the case of simple linear regression the best line will be returned even though the data are not linear. Therefore, to avoid false conclusions, all of the above-mentioned points have to be considered. The leverage residual, DFFITS and Cook's distance of observations are other measures that can be used to assess the quality and robustness of the fit, see ([Sen and Srivastava, 1990](#); [Jobson, 1991](#); [Altman and Krzywinski, 2016b](#)) for more details. In cases where the assumptions are violated, one can use data transformations to mitigate the deviation from the assumptions, or use more sophisticated regression models, such as generalized linear models, non-linear models, and non-parametric regression approaches depending on the type of assumptions one can place on the data.

Outliers and Influential Observations

The presence of outliers can be connected to potential problems that may inflate the apparent validity of a regression model ([Sen and Srivastava, 1990](#); [Jobson, 1991](#); [Altman and Krzywinski, 2016a](#)). In particular, an outlier is a point that does not follow the general trend of the rest of the data. Hence it can show either an extreme value for the response Y , or for any of the predictors X_k , or both. Its presence may be due either to measurement error, or to the presence of a sub-population that does not follow the expected distribution. One might observe one or few outliers when fitting a regression model. An influential point is an outlier that strongly affects the estimates of the regression coefficients. Anscombe's quartet ([Anscombe, 1973](#)) is a typical example used to illustrate how influential points can inflate conclusions. Roughly speaking, to measure the influence of an outlier, one can compute the regression coefficients with and without the outlier. More formal approaches for detecting outliers and influential points are described in [Sen and Srivastava \(1990\)](#), [Jobson \(1991\)](#), [Altman and Krzywinski \(2016a\)](#).

Transformations

As already mentioned above, when the Gauss-Markov conditions are not satisfied ordinary least squares cannot be used. However, depending on deviation from the assumptions, either a transformation can be applied in order to match the assumptions, or other regression approaches can be used. More in general, transformations can be used on the data for wider purposes, for example for centering and standardizing observations when the variables have different magnitude. Other widely used transformations are logarithmic and square-root transforms that can help in linearizing relationships. Additionally, in the context of linear regression, variance-stabilizing transformations can be used to accommodate heteroscedasticity, and normalizing transformations to better match the assumption of normal distribution. Although several transformations have been proposed in the literature, there is no standard approach. Moreover, an intensive use of transformations might be questionable. The reader is referred to ([Sen and Srivastava, 1990](#)) for more details.

Beyond ordinary least squares approaches

As previously stated, linear regression is also known as the regression of the “mean” since the conditional mean of Y given X is modeled as linear combination of the regressors, X , plus an error term. In this case, the least squares approach constitutes the BLUE when the Gauss-Markov conditions hold. However, other types of criteria, such as *quantile regression*, have been proposed (McKean, 2004; Koenker, 2005; Maronna et al., 2006). In particular, quantile regression aims at estimating either the conditional median or other conditional quantiles of the response variable. In this case, the estimates are obtained using linear programming optimization algorithms that solve the corresponding minimization problem. Such types of regression models are more robust than least squares with respect to the presence of outliers.

Advanced Approaches

High Dimensional Regression ($p \gg n$)

Classical linear regression, as described above, requires the matrix $(X^T X)$ to be invertible, this implies that $n \geq p$, where n denotes the number of independent observations (i.e., the sample size) and p the number of variables. Current advance in science and technology allow the measurement of thousands or millions of variables on the same statistical unit. Therefore, one has often to deal with the case of $p \gg n$, where ordinary least squares cannot be applied, and other types of approaches must be used. The solution in such cases is to use penalized approaches such as Ridge regression, Lasso regression, or Elastic net or others (Hastie et al., 2009; James et al., 2013; Tibshirani, 1996, 2011; Zou and Hastie, 2005), where a penalty term, $P(\beta)$, is added to the fitting criteria, as follows

$$(Y - X\beta)^T(Y - X\beta) + \lambda P(\beta)$$

where λ is the so-called *regularization parameter*, which controls the trade-off between bias and variance. In practice, by sacrificing the unbiased property of the ordinary least squares, one can achieve generalization and flexibility. Different penalty terms lead to different regressions methods (Bühlmann and van de Geer, 2011; Hastie et al., 2015) and are also known as *regularization techniques*. The regularization parameter, λ , is usually selected using criteria such as cross-validation.

Other possible approaches include the use of dimension reduction techniques such as principal component analysis or feature selection, such as described in the Chapter *Dimension Reduction Techniques* in this volume.

Ridge regression

The estimates of the regression coefficients are obtained by solving the following minimization problem

$$\hat{\beta}^{\text{Ridge}} = \underset{\beta}{\operatorname{argmin}} \left[\sum_{i=1}^n (Y_i - \beta_0 - \beta_1 x_{i1} - \beta_2 x_{i2} \dots - \beta_p x_{ip})^2 + \lambda \sum_{j=1}^p \beta_j^2 \right] = \underset{\beta}{\operatorname{argmin}} [(Y - X\beta)^T(Y - X\beta) + \lambda \|\beta\|_2^2]$$

where $\lambda > 0$ is a suitable regularization parameter. It is easy to show, since the minimization problem is convex, it has a unique solution. The solution can be computed in a closed form as

$$\hat{\beta}^{\text{Ridge}} = (X^T X + \lambda I)^{-1} X^T Y$$

which corresponds to shrinking the ordinary least square coefficients by an amount that is controlled by λ . Ridge regression can be used when $(X^T X)$ is singular or quasi-singular and ordinary least squares does not provide a unique solution. In fact, in such circumstance $(X^T X + \lambda I)$ is still invertible. Note that, as $\lambda \rightarrow 0$ the penalty plays a “minor” role, thus $\hat{\beta}^{\text{Ridge}}$ tends to $\hat{\beta}$ (i.e., those coefficients obtained by using ordinary least squares), when $\lambda \rightarrow +\infty$ the $\hat{\beta}^{\text{Ridge}}$ tends to zero (i.e., to the so-called intercept-only model). Different values of λ provide a trade-off between bias and variance (larger λ increases the bias, but reduces the variance). A suitable value of λ can be chosen from the data by cross-validation. Although ridge regression can be used for fitting high dimensional data in a more effective way than using ordinary least squares approach, there are however some limitations such as a large bias toward zero for large regression coefficients, and a lack of interpretability of the regression solution since “unimportant” coefficients are shrunk towards zero, but they’re still in the model instead of being killed to zero. As a consequence, the ridge regression does not act as model selection.

Lasso regression

The estimates of the regression coefficients are obtained by solving the following minimization problem

$$\hat{\beta}^{\text{Lasso}} = \underset{\beta}{\operatorname{argmin}} \left[\sum_{i=1}^n (Y_i - \beta_0 - \beta_1 x_{i1} - \beta_2 x_{i2} \dots - \beta_p x_{ip})^2 + \lambda \sum_{j=1}^p |\beta_j| \right] = \underset{\beta}{\operatorname{argmin}} [(Y - X\beta)^T(Y - X\beta) + \lambda \|\beta\|_1]$$

where $\lambda > 0$ is a suitable regularization parameter. The underlying idea in lasso approach is that it seeks a set of sparse solutions meaning that it will set some regression coefficients exactly equal to 0. As a consequence, lasso also performs model selection. Larger is the value of λ , more will be the coefficients set to zero. Unfortunately, the solution of lasso minimization problem is not available in closed form, however it can be obtained by using convex minimization approaches and several algorithms have been

proposed such as the least-angle regression (LARS) (Efron *et al.*, 2004) to efficiently fit the model. Analogously to ridge regression, a suitable value of λ can be chosen from the data by cross-validation.

Overall, lasso has opened a new framework in the so-called *high-dimensional regression models* and several generalizations have been proposed (Bühlmann and van de Geer, 2011; Hastie *et al.*, 2015) to overcome its limitations and to extend the original idea to different regression contexts.

Elastic net regression

The estimates of the regression coefficients are obtained by solving the following minimization problem

$$\begin{aligned}\hat{\beta}^{\text{Elastic net}} &= \underset{\beta}{\operatorname{argmin}} \sum_{i=1}^n \left(Y_i - \beta_0 - \beta_1 x_{i1} - \beta_2 x_{i2} \dots - \beta_p x_{ip} \right)^2 + \lambda_1 \sum_{j=1}^p \beta_j^2 + \lambda_2 \sum_{j=1}^p |\beta_j| \\ &= \underset{\beta}{\operatorname{argmin}} \left[(Y - X\beta)^T (Y - X\beta) + \lambda_1 \|\beta\|_2^2 + \lambda_2 \|\beta\|_1 \right]\end{aligned}$$

where $\lambda_1 > 0$ and $\lambda_2 > 0$ are suitable regularization parameters (Zou and Hastie, 2005). Note that for $\lambda_1 = 0$ one can obtain lasso regression, while the case $\lambda_2 = 0$ corresponds to ridge regression. Different combinations of λ_1 and λ_2 compromise between shrinking and selecting coefficients. Indeed, elastic net was designed to overcome some of the limitations of both ridge regression and lasso regression, since the quadratic penalty term shrinks the regression coefficients toward zero, while the absolute penalty term act as model selection by keeping or killing regression coefficients. For example, elastic net is more robust than lasso when correlated predictors are present in the model. In fact, when there is a group of highly correlated variables, lasso usually selects only one variable from the group (ignoring the others), elastic net allows more variables to be selected. Moreover, when $p > n$ lasso can select at most n variables before saturating, whereas, thanks to the quadratic penalty, elastic net can select a larger number of variables in the model. On the other hand, “unimportant” regression coefficients are often set to zero to perform variable selection.

Other Types of Regressions

Generalized linear models (GLM) are a well-known generalization of the above-described linear model. GLM allow the dependent variable, Y , to be generated by any distribution $f()$ belonging to the exponential family. The exponential family includes normal, binomial, Poisson, and gamma distribution among many others. Therefore GLM constitute a general framework in which to handle different type of relationships.

The model assumes that the mean of Y depends on X by means of a link function, $g()$,

$$E(Y) = \mu = g^{-1}(X\beta)$$

where $E()$ denotes expectation and $g()$ the *link function* (an invertible, continuous and differentiable function). In practice, $g(\mu) = X\beta$, so there is a linear relationship between X and a function of the mean of Y . Moreover, in this context the variance is also function of the mean $\operatorname{Var}(Y) = V(\mu) = V(g^{-1}(X\beta))$.

In this context, the linear regression framework can be reformulated choosing the identity as the link function, Poisson regression corresponds to $\operatorname{Log}()$ as the link function, and binomial regression to choosing Logit , and so on.

The unknown regression coefficients β are typically estimated with maximum likelihood, maximum quasi-likelihood, or Bayesian techniques. Inference can then be carried out in a similar way as for linear regression. A formal description and mathematical treatment of GLM can be found in McCullagh and Nelder (1989), Madsen and Thyregod (2011). GLM are very important for biomedical applications since they include logistic and Poisson regression, which are often used in biomedical science to model binary outcomes or counts data, respectively.

Recently, penalized regression approaches, as those described in section high dimensional regression, have been extended to the generalized linear models. In this context, the *regularization* is achieved by penalizing the log-likelihood function; see (Bühlmann and van de Geer, 2011; Hastie *et al.*, 2015) for more details.

Closing Remarks

Regression constitutes one of the most relevant frameworks of modern statistical inference with many applications to the analysis of biomedical data, since it allows one to study the relationship between a dependent variable Y and a series of p independent variables $X = [X_1 | \dots | X_p]$, from a set of independent observations (x_i, Y_i) , $i = 1, \dots, n$. When the relationship is linear in the coefficients one has linear regression. Despite its simplicity, linear regression allows testing the significance of the coefficients, estimating the uncertainty and predicting novel outcomes. The Gauss-Markov conditions guarantee that the least squares estimator has the BLUE property, and the normality of the residuals allows carrying out inference. When $p > n$, classical linear regression cannot be applied, and penalized approaches have to be used. Ridge, lasso and elastic net regression are the most well known approaches in the context of high dimensional data analysis (Bühlmann and van de Geer, 2011; Hastie *et al.*, 2015). When the

white-noise conditions are violated data transformation of other types of models have to be considered. Analogously, when the relationship is not linear other approaches or non-parametric models should be used.

Nonlinear Regression Models

Audrone Jakaitiene, Vilnius university, Vilnius, Lithuania

© 2019 Elsevier Inc. All rights reserved.

Introduction

Regression was, and still is, a very common tool used by researchers in various fields to express a relationship between one or more explanatory variables (also called predictors or covariates) and a response variable (or outcome). The most frequently employed regression models are linear. However, a linear regression model cannot handle discrete responses, such as categorical outcomes or counts. Sometimes the data itself does not follow a linear pattern. This motivates the use of nonlinear models. One option is to use generalized linear model (GLM), which can represent categorical, binary or other types of responses. Another option is to set up nonparametric regression models, or to perform curve fitting. Therefore, in this article, we will focus on nonlinear regression models, such as logistic, Poisson and negative binomial regressions, with some insights to more generalized nonlinear models.

GLM provide a statistical framework for diverse research problems in various fields, such as medicine, biology, bioinformatics and others. Background information about the most widely used GLMs, such as binary logistic, and Poisson regression can be found in almost any statistical textbook (e.g., Bowers, 2008; Kirkwood and Sterne, 2010; Motulsky, 2014). More advanced information about GLMs can be obtained from recent books in which various modelling peculiarities are addressed, and implementation discussed (e.g., Agresti, 2015; Faraway, 2016; Hosmer *et al.*, 2013). However nowadays, in the era of big data, GLM faces new challenges and still is a significant research topic. A few challenges come from genetic data analysis. Using new DNA sequencing technologies, it is feasible, in terms of cost and time, to sequence all the exomes or complete genomes of large numbers of people. However, as for now, the number of sequenced individuals is much smaller as the number of potential covariates (each individual may have millions of genetic variants, which each may be rare in the population), leading to high dimension and low sample size problems that might not be handled with classical models (Dasgupta *et al.*, 2011). For large p and small n microarray data, Liao and Chin (2007) discuss covariates selection and accurate error estimation issues for logistic regression models. For rare events in high dimensional data, sparse logistic regression is applicable as well (Liu *et al.*, 2009). Qiu *et al.* (2013) discuss bias issues in logistic regression and propose methods for bias adjustment for rare events in large scale data. New methodologies for Poisson and Negative binomial regression have been developed in light of big data and/or rare events, as well (Papastamoulis *et al.*, 2016; Anders and Huber, 2010).

We start with standard notation for linear models. Then we introduce GLM for nominal and count variables, with some insights to other nonlinear modelling technics. The implementation of GLM in R is presented. The main assessment aspects of the models, and the regularization methods are described. Discussion and future directions finalize the article.

Fundamentals

General Linear Model

In a general linear model (LM), we model the response variable, Y , as a linear function of the explanatory or predictor variables, X_k , where $k=1, \dots, K$ and ε is an error term

$$Y = \beta_0 + \beta_1 X_1 + \dots + \beta_K X_K + \varepsilon \quad (1)$$

where β_k are regression parameters, estimated using ordinary least squares. Y and each explanatory variable, X_k , as well as the error term have n observations. The model is *linear in the parameters*. We assume that the errors, ε , are independent and identically distributed such that $E(\varepsilon)=0$, $Var(\varepsilon)=\sigma^2$ and $\varepsilon \sim N(0, \sigma^2)$.

Although linear models are a useful approach, there are some cases when general linear models are inappropriate, namely when possible Y values are restricted (such as categorical or count data), or the variance of Y depends on the mean. Generalized linear models extend the linear model approach to address these issues.

Generalized Linear Models

The purpose of generalized linear model (GLM), as for LMs, is to identify a relationship between a number of covariates and response variables. Following Agresti (2015), a GLM is composed of

- A *random component*, which specifies the response variable, Y , and its probability distribution from an *exponential family* (the most commonly used are Normal, Binomial, and Poisson). The observations of Y are treated as independent.
- A *linear predictor* for k explanatory variables

$$\eta = \beta_0 + \beta_1 X_1 + \dots + \beta_k X_k \quad (2)$$

The linear predictor is linear in the parameters. The explanatory variables can be nonlinear functions of underlying variables, such as interaction term (e.g., $X_4 = X_1 X_3$). In GLM, Y is treated as random, and explanatory variables as fixed, therefore the linear predictor is sometimes called the *systematic component*.

- A smooth and invertible linearizing *link function* $g(\cdot)$, which describes how the mean of the response variable, $E(Y) = \mu$, depends on the linear predictor, $g(\mu) = \eta$.
- A *variance function* $V(\cdot)$, which describes how the variance of the response variable, $Var(Y)$, depends on the mean, i.e., $Var(Y) = \phi V(\mu)$. ϕ is a constant dispersion parameter.

A GLM with a link function $g(\mu) = \mu$, known as the *identity link function*, is called a linear model (Agresti, 2015). Therefore, LM is a special case of GLM.

Next we introduce the two most important GLM for nonlinear modelling of discrete response variables, such as categorical and count data.

Modelling categorical data

The *logistic regression* (LR) model is a common approach for modelling a categorical outcome variable. Categorical variables could be binary decision variables (for example, Yes/No, Present/Absent, Healthy/Disease), or variables with more than two levels (for example, cause of a death – cancer, heart disease, other). If response variable is binary, one will set up a univariable (one explanatory variable) or multivariable (more than one covariate) *binary* (also called binomial) *logistic regression* (BLR). If response variable has more than two levels, one would conduct univariable or multivariable *multinomial logistic regression* (MLR). Nowadays, LR is a classical approach for building prediction or classification methods, and has been widely used in many applications, such as bioinformatics (Tsuruoka et al., 2007), gene classification (Liao and Chin, 2007), genetic association (Cantor et al., 2010; Jostins and McVean, 2016), and neural signal processing (Philiastides et al., 2006).

Binomial logistic regression (BLR). Suppose a response variable, Y , takes the values zero or one and $P(Y=1) = p$. For example, presence (value 1) or absence (0) of a species in a site. We need a model that relates k explanatory variables and the probability, p . As described above, a linear predictor has the form shown in equation (2). We cannot use $\eta = p$ as a link function, as it does not guarantee $0 \leq p \leq 1$. The most popular choice is the *logit* link function

$$\eta = g(\mu) = \text{logit}(\mu) = \log(p/(1-p)) \quad (3)$$

and

$$p = \frac{e^\eta}{1 + e^\eta}$$

Thus, the combination of a linear predictor with the logit link function gives BLR (Faraway, 2016). One obtains the logarithm of the odds of a positive outcome, and straightforward algebraic manipulation transforms this into the probability of the outcome. We use the method of maximum likelihood to obtain estimates of the parameters.

Multinomial logistic regression (or *multinomial regression*, MLR) is an extension of BLR to nominal outcome variables with more than two levels. Following Faraway (2016), suppose random variable Y can have values of a finite number of categories, labeled $1, 2, \dots, J$. Let $p_j = P(Y=j)$ and $\sum_{j=1}^J p_j = 1$. In MLR, as in BLR, we want to set up a model that links the probabilities, p_j , with the explanatory variables, X_k . Similarly

$$\eta_j = \beta_{0j} + \beta_{1j}X_1 + \dots + \beta_{Kj}X_K = \log \frac{p_j}{p_c}, j = 1, \dots, J-1$$

where we use category J as a reference and

$$p_j = \frac{e^{\eta_j}}{1 + \sum_{j=1}^{J-1} e^{\eta_j}}$$

$$p_J = 1 - \sum_{j=1}^{J-1} p_j$$

It makes no difference which category we choose as the reference, although there may be choices that are more convenient for interpretation. The MLR model estimates a separate binary logistic regression model for each category variable. The result is $J-1$ binary logistic regression models. Each one specifies the effect of the predictors on the probability of success in that category, in comparison to the reference category. As for BLR, we use the method of maximum likelihood (ML) to obtain estimates of the parameters.

Modelling count data

For count data, for example, the number of emerging seedlings in a plot, the number of ticks on red grouse chicks, or clutch sizes of storks (Bolker et al., 2009), the response variable is discrete, positive and, typically, not bounded. If the count is bounded, logistic regression could be considered or, if the count is sufficiently large, linear regression might be used.

Variables that denote the number of occurrences of an event, or object in a certain unit of time or space, are distributed according to the Poisson distribution (Motulsky, 2014). We assume that the events occur randomly, independently of one another, and with an average rate that does not change over time. Therefore, if $Y \sim \text{Pois}(\mu)$, we might set up a *Poisson regression*

model in which the linear predictor is linked via the log link function, that is:

$$\log(\mu) = \eta = \beta_0 + \beta_1 X_1 + \dots + \beta_K X_K$$

For a Poisson distribution, the variance must be equal the mean, i.e., $E(Y) = \text{Var}(Y) = \mu$. However, count data are often highly variable, due to heterogeneity, and exhibit variance that is larger than mean; this is called *overdispersion*.

The *Negative binomial distribution* handles overdispersion by using an extra parameter to account for it. Typically the mean response μ is linked to the linear predictor as follows:

$$\eta = \beta_0 + \beta_1 X_1 + \dots + \beta_K X_K = \log \frac{\mu}{\mu + \phi}$$

ϕ is fixed, and is additional parameter that must be estimated.

Some datasets show greater frequencies of zero counts than the Poisson or Negative binomial models allow. For this case, zero-inflated Poisson or Negative binomial regressions can be employed (see [Agresti, 2015](#)).

Other Nonlinear Techniques

As described above, LM is special case of GLM. A GLM is special case of a *generalized additive model* (GAM), where the linear predictor is replaced by smooth functions of the explanatory variables

$$g(\mu) = \sum_{k=1}^K s_k(X_k)$$

where $s_k(\cdot)$ is an unspecified smooth function of predictor k . So, when s_k is a linear function, GAM becomes GLM.

More generally, we have *nonlinear regression* when the response mean is a nonlinear function of the parameters

$$E(Y) = f(X; \beta)$$

where f is a known function of the explanatory variables and parameters. For example, we can consider a model for tumor or population growth ([Agresti, 2015](#))

$$E(Y) = \frac{\beta_0}{1 + e^{-(\beta_1 + \beta_2 X)}}$$

Up to now f linearly or nonlinearly depends on parameters, which we call a parametric approach. Parameters have an empirical interpretation. In a nonparametric approach, we can select f from some smooth family of functions. All we have to assume are the degree of smoothness and continuity of f ([Faraway, 2016](#)). There is no formulaic way of describing the relationship between the covariates and the response. The nonparametric approach might be a relevant tool for modelling unknown data, when we have little idea about an appropriate form of the model. Nonparametric regression estimators, also known as *smoothers*, could be kernel or spline methods. Both of them suffer from outlier issues in the data. [Cleveland \(1979\)](#) proposed the algorithm *lowess* or *loess* (locally weighted scatter plot smoothing) as an outlier resistant method based on local polynomial fits. For the implementation of the latter algorithm the function *loess()* has been implemented in R.

However, if one has proper information about the appropriate model family, a parametric model should be considered.

GLM Implementation in R

Linear and GLM analysis can be conducted using R, SAS, Stata, SPSS and other general purpose statistical software. We discuss only R, and give links to examples. However, the choice of the software is less essential when one understands and can interpret the results, as the outputs are quite similar irrespective of the software selected.

In R, a standard GLM can be fitted using the *glm* function from the package *stats*, which is similar to the *lm* function for fitting linear models.

The syntax of the *glm* function is

$$\text{glm}(\text{formula}, \text{family}, \text{data}, \text{weights}, \text{subset}, \dots)$$

We will give some details only on the *formula*, *family* and *data* arguments as the remaining list of arguments and their usage can be found on the *glm* function webpage.

The argument *formula* should be specified as follows

$$Y \sim X_1 + X_2$$

where Y is the response variable, coded 0/1 for BLR, and X_1 and X_2 are the explanatory variables, which could be continuous or categorical variables. The latter should be coded as a dummy variable with values 0/1, as well. If not encoded by a dummy variable, by default, the first level alphabetically will be associated with $Y=0$, and the second with $Y=1$. One should be careful with categorical data that have more than 2 levels ([Bowers, 2008](#); [Suits, 1957](#)) (Additional reading about how to code dummy variables in R: see Relevant Website section). All specified variables must be in the workspace or in the data frame passed in the *data* argument.

For the *family* argument, one has various choices of distributions of response variables, together with options for a link function. Normal, binomial and Poisson regression would use the following *family* specifications

```
gaussian(link="identity")
binomial(link="logit")
poisson(link="log")
```

The implementation of a binary logistic regression (BLR) model would be as follows

```
Mod_BLR <- glm(Response ~ Expl_1 + Expl_2, data=inputData, family=binomial(link="logit"))
summary(Mod_BLR)
predicted <- predict(Mod_BLR, newData, type="response")
```

The *glm* function will build the logistic regression model, *Mod_BLR*, based on the given formula. When we use the *predict* function on this model, it will predict the *log(odds)* of the response variable *Y*.

We cannot implement a multinomial logistic model (MLM) using the *glm* function. Instead, we need to employ the *multinom* function from the *nnet* package

```
library(nnet)
Mod_MLM <- multinom(Response ~ Expl_1 + Expl_2, data=inputData)
summary(Mod_MLM)
```

Implementation of standard Poisson regression is possible using the *glm* function, e.g.,

```
Mod_Pois <- glm(Response ~ Expl_1 + Expl_2, family="poisson", data=inputData)
summary(Mod_Pois)
predict(Mod_Pois, newData, type="response")
```

To implement a negative binomial model (NBM), we need the *glm.nb* function from the *MASS* package, for which we need to provide only the formula and data frame

```
library(MASS)
Mod_NBM <- glm.nb(Response ~ Expl_1 + Expl_2, data=inputData)
summary(Mod_NBM)
predict(Mod_NBM, newData, type="response")
```

The implementation of zero-inflated and zero-truncated models, with examples in R, for example, can be found in the webpages of The Institute for Digital Research and Education, UCLA (see Relevant Websites).

For the implementation of nonlinear regression models in R, one can consider using the *nlstools* package (Baty *et al.*, 2015).

Fitting Regression Models

The following steps are necessary when fitting regression models:

1. *Model selection/specification.* When one considers multivariable analysis, the selection of variables (or features) is essential. In general, there are two approaches to feature selection: *forward* and *backward*. In the forward approach, we start with a single explanatory variable in a model, and extend it by including additional variables. We retain only the variables whose p-values are less than confidence level in the model. In the backward approach, we start with a model including all explanatory variables. We sequentially eliminate the variables with the largest p-values (those greater than confidence level). Inclusion or exclusion of variables is performed sequentially. If there are no further variables to include or exclude, the model selection process is terminated. For model selection, the Akaike Information Criteria (AIC) or Bayesian information criterion (BIC) are often used. AIC penalizes a model for having many parameters. A model with better fit has smaller AIC/BIC (for more details, see Symonds and Moussalli, 2011). BIC penalizes a model more severely for the number of parameters compared to AIC. Detailed discussion about the use of AIC vs BIC is provided in Aho *et al.* (2014). To obtain the p-values of the parameters, formula and AIC in R, one can use the *summary()* function for the model. The BIC value can be retrieved using the function *BIC()* for the model.
2. *Model estimation.* Parameter estimation of the selected model will be performed by the selected function. Parameter estimates will be reported in the output of the *summary()* function. For the parameter information alone, one can apply *coef()* function.
3. *Adequacy.* One should check how well the estimated model fits the data. In R there are several functions that can be used, such as *residuals()*, to extract information about residuals of the estimated model; *fitted()* returns the fitted values of the response, using the estimated model, and *predict()* returns the predicted values of the response, using the estimated model. The default predictions are provided on the logit scale (i.e., predictions are made in terms of log odds), while using *type="response"* gives the predicted probabilities.

4. *Inference*. As the last step, we can calculate confidence intervals, perform hypothesis testing, and interpret the results. We calculate confidence intervals for the estimated parameters using the `confint()` function. For two model differences one can use `anova()` function, with the additional optional `test="Chisq"`. A likelihood ratio test comparing candidate models can be performed using the `lrtest()` function from the package `lmtest`.

More information about reporting and selection of LR is provided in Bagley *et al.* (2001) and Bursac *et al.* (2008), respectively. R has a separate package `glmulti` for automated GLM feature selection and multi-model inference. It handles high dimensional data and parallel version is available (Calcagno and de Mazancourt, 2010).

Regularization Methods

In fitting GLM, typically, ML is applied, however sometimes *regularization methods* are used to modify ML in order to avoid interpretability and overfitting issues. ML cannot distinguish covariates with little or no influence, and the variance of parameters becomes infinite for large p and small n problems. Of course, we can think about smaller subsets of the predictors, or apply some method of dimension reduction. Other way, keeping all covariates in the analysis, is to add a term when maximizing the log-likelihood, $L(\beta)$, of the model, which smooths the ordinary estimates. Thus we maximize

$$L^*(\beta) = L(\beta) - s(\beta)$$

where $s(\cdot)$ is a function, defined such that $s(\beta)$ decreases when the elements of β are smoother, in some sense, such as uniformly closer to 0. This method is called the *penalized likelihood* (Agresti, 2015).

A variety of penalized-likelihood methods use L_q -norm smoothing function

$$s(\beta) = \lambda \sum_{k=0}^K |\beta_k|^q$$

for $q \geq 0$ and $\lambda \geq 0$. The response and explanatory variables should be standardized.

Regularization methods that use a quadratic penalty term, $q=2$, are called L_2 -norm penalty methods. In the case of LM, this is known as ridge regression. Fitting a model with the L_1 -norm penalty, $q=1$, it is called the *lasso* (least absolute shrinkage and selection operator) method. For ridge regression, lasso, and other regularization methods, the `glmnet` package can be used in R.

Discussion and Future Directions

Some data has a grouped, nested or hierarchical structure. Repeated measures, longitudinal, and multilevel data, consist of several observations taken on the same individual or group. This may induce a correlation structure in the error terms, ϵ . Also random effects may not be negligible. Therefore, for such data, a mixed effect modelling strategy might be considered (Bolker *et al.*, 2009; McCulloch and Neuhaus, 2001).

The implementation of GLM might result overfitting for high-dimensional data, which might come not only from genetic but also biomedical imaging, signal processing, image analysis, language recognition, and financial data. Regularization methods are especially useful when the number of model parameters is extremely large (Wu *et al.*, 2009; Meier *et al.*, 2008; Roth and Fischer, 2008; Friedman *et al.*, 2010; Ogutu *et al.*, 2012). Tran *et al.* (2015) point out that for large p and huge n , ordinary ML fitting may not be possible, and new methods might be needed. According to Agresti (2015), variable selection methods for large p fall into two types: dimension-reduction methods (stepwise methods, penalized regularization), and identification of relevant effects using significance tests, with adjustment for multiplicity (such as the false discovery rate (FDR)). As another dimension reduction method, one might consider principal component analysis.

As another approach to modelling, one can use Bayesian approach (Jostins and McVean, 2016). However, when dealing with large p , Bayesian inference is perhaps even more challenging than frequentist inference (Agresti, 2015).

Closing Remarks

Nonlinear regression models are a very broad topic. The most frequently used approaches have been concisely discussed, above. Some insights about which methods are appropriate for high-dimensional data, specifically when sample size is small and the parameter number is large, have been provided. All of the described methods are widely used, in many fields, such as biology, medicine, epidemiology, image analysis, language detection, finance. We expect that, due to rapid technological development, nonlinear models will play an even larger role in both theoretical and applied research in the future.

Biographical Sketch

Audrone Jakaitiene is professor and senior researcher at Vilnius university. She defended her PhD thesis in physical sciences (Informatics 09P) in 2001. Title of the thesis “The Algorithms of Competing Risk Regression Models”, in which competing risks were forecasted using regression models and neural networks. Later A. Jakaitiene worked in Lithuanian and EU institutions developing her modelling skills in social, physical and biomedical sciences. As of 2005, her research paper topics could be split in three fields: (1) modelling and forecasting of Lithuanian, European Union and global economic indicators; (2) Analysis of biomedical data, with special interest to modelling of large-scale genetic data; (3) Educational data research covering international databases and an integrated analysis of Lithuanian data. In 2005–2016, she published 40 scientific papers (15 in Clarivate Analytics Web Of Science, H-index 4), participated in more than 30 conferences. From 2011 she is head of Bioinformatics and Biostatistics center at Human and Medical Genetics Department, Medical Faculty, Vilnius university.

Parametric and Multivariate Methods

Luisa Cutillo, University of Sheffield, Sheffield, United Kingdom; and Parthenope University of Naples, Naples, Italy

© 2019 Elsevier Inc. All rights reserved.

Parametric Statistical Inference

Statistics can be broken into two basic types. The first is known as descriptive statistics. This is a set of methods used to describe data that we have collected. The second type of statistics is inferential statistics. This is a set of methods used to make a generalization, estimate, prediction, decision. In inferential statistics a population is a general class of objects (genes, tissues, cell, etc.) for which we want to make an inferential statement. A set of observed items from the population is called a sample. The need for statistical inference comes from the existence of measurement errors. As an example, in experimental biological data there is both biological and technical variability, and hence the need to control and quantify variability. The use appropriate inferential tools may leverage both the current study and previous information to provide a reproducible inference. In statistical inference, the sample is used to make inferences about the population, meaning that the sample needs to be representative of the population and not biased. The majority of the inferential methods are based on the assumption that the samples are independent of each other. However, correlation is often induced. Examples of biological correlations are those between animals from the same litter (i.e., family correlation) or repeated measurements on the same subject. Another example of correlation is the one related to the so called batch effects. Suppose you replicate an experiment in two different labs; it is likely that the measurements taken within each lab are more similar to each other than to the measurements taken in different labs. The cause of these similarities might be the lab environment, batches of reagents, feed, or the operator who performed the experiment and made the measurements. These similarities induce correlation and if we neglect it by treating samples as if they are independent, we can introduce large errors into the analysis, which typically leads to a high error rate.

Parametric statistics is that part of statistics that assumes sample data follow a probability distribution based on a fixed set of parameters. On the other hand, in a non-parametric model, the parameter set is not fixed and can vary in case new relevant information is collected. A parametric model relies on specific assumptions about a given population and, when such assumptions are correct, parametric methods will produce more reliable estimates than non-parametric methods. Conversely, when the assumptions are not correct they have a greater chance of failing, and hence are not a robust statistical method. However the great advantage of parametric formulae is that they are simple and fast to compute. The simplicity of a parametric model, when accompanied by suitable diagnostic statistics, can compensate for the lack of robustness.

Maximum Likelihood Estimation

Given of a subset of individuals from within a statistical population, we need to estimate the characteristics of the whole population. The likelihood function expresses the evidence contained in a sample that is relevant for inferring the parameters of a given a statistical model. A likelihood function is a probability distribution considered as a function of its distributional parameterization argument. As an example, consider an observable random variable, X , modelled by a probability density function depending on the parameter θ .

We can consider the function $L(\theta|x) = P(X=x|\theta)$ as a likelihood function of θ , for a specific value x of X . This gives a measure of how likely any particular value of θ is, given that we know x is a realization of X . Suppose now that, $x_1, x_2, \dots, x_n$ is a sample of n independent and identically distributed observations, distributed according to an unknown probability density function, $f_0(\cdot)$. The function, f_0 , is usually assumed to belong to a specific parametric model, a family of distributions, $\{f(\cdot|\theta), \theta \in \Theta\}$ (where θ is a vector of parameters for this family), so that $f_0 = f(\cdot|\theta_0)$. The values of the set of parameters θ_0 are unknown. It is desirable to find an estimator which would be as close to the true value θ_0 as possible. To solve this task we can use the method of maximum likelihood that can be summarized in the following steps.

First we need to specify the joint density function for all observations. Hence, given an independent and identically distributed sample, $x_1, x_2, \dots, x_n$, the joint density function is

$$f(x_1, x_2, \dots, x_n|\theta) = f(x_1|\theta)f(x_2|\theta) \dots f(x_n|\theta) \quad (1)$$

If we consider the observed values $x_1, x_2, \dots, x_n$ to be fixed parameters, and θ as the function's variable, we can rewrite (1) as the likelihood function:

$$L(\theta) = f(x_1, x_2, \dots, x_n|\theta) = \prod_{i=1}^n f(x_i|\theta) \quad (2)$$

Usually, it is convenient working with the log-likelihood, the natural logarithm of the likelihood function:

$$l(\theta) = \ln(L(\theta)) = f(x_1, x_2, \dots, x_n|\theta) = \sum_{i=1}^n \ln(f(x_i|\theta)) \quad (3)$$

Indeed we can use the fact that the logarithm is an increasing function so it will be equivalent to maximizing the log-likelihood. The maximum likelihood estimator (MLE) of θ is the value, θ_0 , that maximizes (3). In the following we provide a few examples of MLE under three different parametric models, namely Normal, Gamma, and Poisson.

Normal Example

Consider the random variables, $X_1, X_2, \dots, X_n$ to be independent and identically distributed (iid) as a normal, $N(\mu, \sigma)$. Their density can be written as:

$$f(x_1, x_2, \dots, x_n | \mu, \sigma) = \prod_{i=1}^n \frac{1}{\sigma \sqrt{2\pi}} \exp\left(-\frac{(x_i - \mu)^2}{2\sigma^2}\right) \quad (4)$$

Interpreting this density as a function of the two parameters, μ and σ , the log-likelihood can be written as:

$$l(\mu, \sigma) = -n \ln \sigma - \frac{n}{2} \ln(2\pi) - \frac{1}{2\sigma^2} \sum_{i=1}^n (x_i - \mu)^2 \quad (5)$$

Given that:

$$\begin{aligned} \frac{\partial l}{\partial \mu} &= \frac{1}{\sigma^2} \sum_{i=1}^n (x_i - \mu) \\ \frac{\partial l}{\partial \sigma} &= -\frac{n}{\sigma} + \sigma^{-3} \sum_{i=1}^n (x_i - \mu)^2 \end{aligned} \quad (6)$$

it comes that the MLE of μ is equal to the sample mean, $\hat{\mu}$, and the MLE of σ is equal to the unadjusted sample variance, $\hat{\sigma}$:

$$\begin{aligned} \hat{\mu} &= \frac{1}{n} \sum_{i=1}^n x_i \\ \hat{\sigma} &= \sqrt{\frac{1}{n} \sum_{i=1}^n (x_i - \mu)^2} \end{aligned} \quad (7)$$

Poisson Example

Assume, $X_1, X_2, \dots, X_n$ are iid Poisson random variables with the marginal frequency function, $P(X=x) = \frac{\lambda^x e^{-\lambda}}{x!}$. The log likelihood will thus be:

$$l(\lambda) = \sum_{i=1}^n (x_i \ln \lambda - \lambda - \ln x_i!) = \lambda \sum_{i=1}^n x_i - n \lambda - \sum_{i=1}^n \ln x_i! \quad (8)$$

whose derivative would be:

$$l(\lambda)' = \frac{1}{n} \sum_{i=1}^n x_i - n = \bar{X} - n \quad (9)$$

hence the MLE of λ , maximum of Eq. (8), is $\hat{\lambda} = \bar{X}$. Note that the MLE agrees with the method of moments in this case.

Gamma Example

In the last two examples the function l was actually concave and, equating the derivatives to zero, we were able to find a maximum of the log-likelihood in closed form. This is not always the case. Consider a final example where $X_1, X_2, \dots, X_n$ are iid Gamma distributed variables with marginal density:

$$f(x|\alpha, \lambda) = \frac{1}{\Gamma(\alpha)} \lambda^\alpha x^{\alpha-1} e^{-\lambda x}$$

The log-likelihood can be written as:

$$l(x|\alpha, \lambda) = \sum_{i=1}^n [\alpha \ln \lambda + (\alpha - 1) \ln x_i - \lambda x_i - \ln \Gamma(\alpha)] \quad (10)$$

If we try to maximize (10), we end up with a nonlinear equation in α that cannot be solved in closed form. In this situation we could employ a so-called *root-finding* method, exploiting the fact that when a function is continuous, and changes signs on an interval, it admits at least one zero on that interval. For this particular problem there are already coded (e.g., in Matlab and e.g., in Matlab and R) general optimization methods, that also provide a confidence interval.

Evaluating an Estimator

Supposing that we are given a random sample, $X_1, X_2, \dots, X_n$, such that each random variable, X_i , has the same distribution as $X \sim f(X|\theta)$. Let's assume that θ is an unknown parameter to be estimated. For example, θ might be the expected value of a random variable, $\theta = E(X)$. To estimate θ , we collect some data and we define a point estimator, $\hat{\theta}$, that is a function of the random sample, i.e., $\hat{\theta} = h(X_1, X_2, \dots, X_n)$. For example if $\theta = E(X)$, we might choose an estimator to be the sample mean, $\hat{\theta} = \frac{1}{n} \sum_{i=1}^n X_i$.

There are many possible estimators for θ , and in the previous paragraph we described the MLE approach. The questions we want to address here are: how can we make sure that an estimator is a good one? How do we compare different possible estimators? As an answer there is a list of some desirable properties that we would like our estimators to have. Indeed, a good estimator should be able to give us values that approach the real value of θ . To clarify this notion, we provide some definitions and examples in the following section, defining three main desirable properties for point estimators.

Bias

The first desirable property of a point estimator is related to the estimator's bias. The bias, $B(\hat{\theta})$, of an estimator, $\hat{\theta}$, tells us on average how far $\hat{\theta}$ is from the real value of θ . Let $\hat{\theta} = h(X_1, X_2, \dots, X_n)$ be a point estimator of θ . The bias of the point estimator $\hat{\theta}$ is defined by

$$B(\hat{\theta}) = E[\hat{\theta}] - \theta. \quad (11)$$

Intuitively, we would expect that a *good* estimator has a bias that is close to 0, indicating that on average, $\hat{\theta} \sim \theta$. We would like to point out that the value of the *bias* might depend on the actual value of the parameter θ , implying that $B(\hat{\theta})$ might be large or small according to the specific value θ assumes. Hence, another desirable property is that an estimator is *unbiased*. If $\hat{\theta} = h(X_1, X_2, \dots, X_n)$ is a point estimator of θ , we say that it is an *unbiased* estimator of θ if $B(\hat{\theta}) = 0$, for all possible values of θ . It is very important to note that, if an estimator is unbiased, it is not necessarily a good estimator. To clarify this concept consider the following example.

Example 1

As before assume that we are given a random sample, $X_1, X_2, \dots, X_n$, such that each random variable, X_i , has the same distribution as X . It is easy to show that the sample mean, $\hat{\theta} = \bar{X}$, and $\hat{\theta}_1 = X_1$ are both unbiased estimators of $\theta = E(X)$. Indeed we have:

$$\begin{aligned} B(\hat{\theta}) &= E[\hat{\theta}] - \theta \\ &= E[\bar{X}] - \theta \\ &= E[X] - \theta = 0 \end{aligned}$$

and

$$\begin{aligned} B(\hat{\theta}_1) &= E[\hat{\theta}_1] - \theta \\ &= E[X_1] - \theta \\ &= E[X] - \theta = 0 \end{aligned}$$

Mean Squared Error

We can guess that $\hat{\theta}_1$ should be a worse estimator with respect to the sample mean $\hat{\theta} = \bar{X}$. Therefore, we need to introduce other measures to ensure the goodness of an estimator. A very common measure is the mean squared error, (MSE). The mean squared error of a point estimator $\hat{\theta}$, referred to as $MSE(\hat{\theta})$, is defined as

$$MSE(\hat{\theta}) = E[(\hat{\theta} - \theta)^2] \quad (12)$$

Note that, as it is defined, the MSE is a measure of the distance between $\hat{\theta}$ and θ , thus a smaller MSE usually suggests of a better estimator.

Example 2

As in the *Example 1*, assume that we are given a random sample, $X_1, X_2, \dots, X_n$, such that each random variable, X_i , has the same distribution as X . Assume now we know that $E(X) = \theta$ and $var(X) = \sigma^2$. We have already shown that the sample mean $\hat{\theta} = \bar{X}$ and $\hat{\theta}_1 = X_1$ are both unbiased estimators of θ . In order to compare the two estimators, let's compute $MSE(\hat{\theta})$ and the $MSE(\hat{\theta}_1)$:

$$\begin{aligned} MSE(\hat{\theta}) &= E[(\hat{\theta} - \theta)^2] \\ &= E[(\bar{X} - \theta)^2] \\ &= var(\bar{X} - \theta) + (E[\bar{X} - \theta])^2 \end{aligned}$$

and

$$\begin{aligned} \text{MSE}(\hat{\theta}_1) &= E\left[(\hat{\theta}_1 - \theta)^2\right] \\ &= E[(X_1 - E(X_1))^2] \\ &= \text{var}(X_1) = \sigma^2 \end{aligned}$$

Note that, since θ is constant, $\text{var}(\bar{X} - \theta) = \text{Var}(\bar{X})$. Moreover it is easy to see that $E[\bar{X} - \theta] = 0$. As a consequence we can write:

$$\begin{aligned} \text{MSE}(\hat{\theta}) &= \text{var}(\bar{X}) \\ &= \frac{\sigma^2}{n} \end{aligned} \quad (13)$$

In conclusion, $\forall n > 1$

$$\text{MSE}(\hat{\theta}_1) > \text{MSE}(\hat{\theta}) \quad (14)$$

Hence, even if $\hat{\theta}$ and $\hat{\theta}_1$ are both unbiased estimators of the population mean, θ , $\hat{\theta}$ is a better estimator due to the fact that it has a smaller MSE. In general, if $\hat{\theta}$ is a point estimator for a population parameter, θ , we can write:

$$\begin{aligned} \text{MSE}(\hat{\theta}) &= E\left[(\hat{\theta} - \theta)^2\right] \\ &= E[(\bar{X} - \theta)^2] \\ &= \text{var}(\hat{\theta} - \theta) + \left(E[\hat{\theta} - \theta]\right)^2 \\ &= \text{var}(\hat{\theta}) + B(\hat{\theta})^2 \end{aligned} \quad (15)$$

Consistency

Given a point estimator, another important property that we should discuss is *consistency*. We could say that an estimator $\hat{\theta}$ is consistent if it converges to the real value of θ as the sample size n increases. More formally, Let $\hat{\theta}_1, \hat{\theta}_2, \dots, \hat{\theta}_n$, be a sequence of point estimators of θ . We say that $\hat{\theta}_n$ is a *consistent estimator* of θ , if

$$\lim_{n \rightarrow \infty} P(|\hat{\theta}_n - \theta| \geq \epsilon) = 0, \forall \epsilon > 0. \quad (16)$$

An important result, that enables an easier evaluation of consistency for an estimator, is that if:

$$\lim_{n \rightarrow \infty} \text{MSE}(\hat{\theta}_n) = 0 \quad (17)$$

then $\hat{\theta}_n$ is a consistent estimator of θ .

To illustrate how we can prove the consistency of an estimator, consider the results in *Example 2*. We could show the consistency of $\hat{\theta}_n = \bar{X}$ by looking at its MSE. Indeed we found previously that in this case $\text{MSE}(\hat{\theta}_n) = \frac{\sigma^2}{n}$. Hence, the (17) is verified. From this, we can conclude that $\hat{\theta}_n = \bar{X}$ is a consistent estimator for θ .

Multivariate Statistics

Data generally will consist of a number of variables recorded on a number of individuals. As an example consider weights, ages, and sexes of a sample of mice analyzed in an experiment. Usually, data collected on n individuals over q variables, say $x_1, \dots, x_p$, will be arranged in an $n \times q$ data matrix, with rows denoting individuals and the columns denoting variables:

$$X = \begin{bmatrix} x_{1,1} & x_{1,2} & \dots & x_{1,q} \\ x_{2,1} & x_{2,2} & \dots & x_{2,q} \\ \vdots & \ddots & \ddots & \vdots \\ x_{n,1} & x_{n,2} & \dots & x_{n,q} \end{bmatrix}$$

where $x_{i,j}$ is the value of variable x_j for individual i . Of course, the measurements in the i th row, namely, $x_{i1}, \dots, x_{ip}$, which are the measurements on the same individual, are correlated. If we arrange them as a column vector $\mathbf{x}_i$ defined as

$$\mathbf{x}_i = \begin{bmatrix} x_{i,1} \\ x_{i,2} \\ \vdots \\ x_{i,q} \end{bmatrix}$$

then $\mathbf{x}_i$ can be viewed as a multivariate observation (Zelterman, 2015; Johnson and Wichern, 2007; Rencher, 2012). Thus, the n rows of matrix X correspond to n multivariate observations, and the measurements within each $\mathbf{x}_i$ are usually correlated. On the other hand usually, $x_1, \dots, x_n$ are assumed to be uncorrelated or statistically independent but this may not always be true. Note that if the set of these n units constitutes the entire finite set of all possible individuals, then we have data available on the entire reference population. However, usually the data are obtained through a survey in which, on each of the individuals, all p characteristics are measured. Such a situation represents a multivariate sample. A sample represents the underlying population from which it is taken adequately or poorly. As a consequence, any summary derived from it merely represents the true population summary.

A very intuitive and immediate way of getting in touch with a multivariate dataset is to visualise it, before even computing any descriptive statistics. A two-dimensional scatter plot is a scatter plot matrix that arranges all possible two-way scatter plots in a $q \times q$ matrix. These displays can be enhanced with brushing, in which individual points or groups of points can be selected in one plot, and simultaneously highlighted in the other plots. See as a reference Fig. 1, where we show a scatter plot of the Fisher-Anderson iris data using the *R* function *pairs*. The most famous data set in multivariate analysis is the Iris data, analyzed by Fisher (1936) based on data collected by Anderson (1935). There are fifty specimens each of three species of iris: *setosa*, *versicolor*, and *virginica*. There are four variables measured on each plant: sepal length, sepal width, petal length, and petal width. Thus $n=150$ and $q=4$. Fig. 1 contains the corresponding scatter plot matrix, with species indicated by colours. We can use Fig. 1 as a starting diagnostic on the data. Indeed, we can note that the three species separate fairly well, with *setosa* especially distinct from the other two.

Basics

To analyse a multivariate data set derived from several mutually dependent variables, we need to find few basic quantities to summarise it. In univariate data there is only one variable under study, and we usually describe it by the population or sample mean, variance, skewness, and kurtosis. Similarly, for multivariate data we can extend such concepts. Let $\mathbf{x} = (x_1, \dots, x_q)^t$ be the $q \times 1$ random vector corresponding to the multivariate population under consideration. Let $\mu_i = E(x_i)$ and $\sigma_{i,i} = \text{var}(x_i)$ be respectively the population mean and variance of x_i . Furthermore, let $\sigma_{i,j} = \text{cov}(x_i, x_j)$ be the population covariance between x_i and x_j . A mean vector $E(\mathbf{x})$ of a multivariate variable is defined as the element-wise application of the expectation to a vector of random variables. That is:

$$E(\mathbf{x}) = \begin{bmatrix} E(x_1) \\ E(x_2) \\ \vdots \\ E(x_q) \end{bmatrix} = \begin{bmatrix} \mu_1 \\ \mu_2 \\ \vdots \\ \mu_q \end{bmatrix} = \boldsymbol{\mu}$$

Moreover, the population variance can be generalised to be the matrix of all the population variances and covariances. Specifically, we can write the variance-covariance matrix of $\mathbf{x}$ as:

$$\begin{aligned} (\boldsymbol{\Sigma}) = (\sigma_{i,j}) &= \begin{bmatrix} \sigma_{1,1} & \sigma_{1,2} & \dots & \sigma_{1,q} \\ \sigma_{2,1} & \sigma_{2,2} & \dots & \sigma_{2,q} \\ \vdots & \ddots & & \\ \sigma_{q,1} & \sigma_{q,2} & \dots & \sigma_{q,q} \end{bmatrix} \\ &= \begin{bmatrix} \text{var}(x_1, x_1) & \text{cov}(x_1, x_2) & \dots & \text{cov}(x_1, x_q) \\ \text{cov}(x_2, x_1) & \text{var}(x_2, x_2) & \dots & \text{cov}(x_2, x_q) \\ \vdots & \ddots & & \vdots \\ \text{cov}(x_q, x_1) & \text{cov}(x_q, x_2) & \dots & \text{var}(x_q, x_q) \end{bmatrix} \end{aligned}$$

As observed previously, there usually exists dependence between $x_1, \dots, x_q$, hence we are interested in measuring the degree of linear dependence between them. Specifically, this is often measured using correlations. Let

$$\rho_{i,j} = \frac{\text{cov}(x_i, x_j)}{\sqrt{\text{var}(x_i)\text{var}(x_j)}} = \frac{\sigma_{i,j}}{\sqrt{\sigma_{i,i}\sigma_{j,j}}} \quad (18)$$

Fig. 1 A scatter plot matrix for the Fisher-Anderson iris data. In each plot, red indicates *setosa* plants, green indicates *versicolor*, and blue indicates *virginica*.

be the Pearson's population correlation coefficient between x_i and x_j . We define the population correlation matrix as:

$$\rho = (\rho_{ij}) = \begin{bmatrix} \rho_{1,1} & \rho_{1,2} & \cdots & \rho_{1,q} \\ \rho_{2,1} & \rho_{2,2} & \cdots & \rho_{2,q} \\ \vdots & \ddots & \ddots & \vdots \\ \rho_{q,1} & \rho_{q,2} & \cdots & \rho_{q,q} \end{bmatrix} = \begin{bmatrix} 1 & \rho_{1,2} & \cdots & \rho_{1,q} \\ \rho_{2,1} & 1 & \cdots & \rho_{2,q} \\ \vdots & \ddots & \ddots & \vdots \\ \rho_{q,1} & \rho_{q,2} & \cdots & 1 \end{bmatrix}$$

Note that both (Σ) and ρ are symmetric by construction. Further, the concept of skewness is generalised as:

$$\text{multivariate skewness } \beta_{1,q} = E[(\mathbf{x} - \mu)'(\Sigma)(\mathbf{x} - \mu)]^3 \quad (19)$$

and the kurtosis is generalised as:

$$\text{multivariate kurtosis } \beta_{2,q} = E[(\mathbf{x} - \mu)'(\Sigma)(\mathbf{x} - \mu)]^2 \quad (20)$$

The quantities just introduced, provide a basic summary of a multivariate population. Of course, when we have a q -variate random sample, $\mathbf{x}_1, \dots, \mathbf{x}_n$, of size n , with the n by p data matrix, $\mathbf{X}$, defined as

$$\mathbf{X} = \begin{bmatrix} x_1' \\ x_2' \\ \vdots \\ x_n' \end{bmatrix} \in \mathcal{R}^{n \times q}$$

we define,

$$\text{sample mean vector : } \bar{\mathbf{x}} = n^{-1} \sum_i^n \mathbf{x}_i \quad (21)$$

$$\text{sample variance – covariance matrix : } \mathbf{S} = (n - 1)^{-1} \sum_i^n (\mathbf{x}_i - \bar{\mathbf{x}})(\mathbf{x}_i - \bar{\mathbf{x}})' \quad (22)$$

$$= (n - 1)^{-1} \mathbf{X}'\mathbf{X}$$

Similarly we can derive skewness and kurtosis.

Many multivariate problems involve data reduction, description and estimation. As a general theme, most of the situations either require some matrix decomposition and transformation or use a distance-based approach. Distributional assumptions, such as multivariate normality, are very helpful in assessing the quality of estimation and make the multivariate statistics *parametric*.

Main Multivariate Techniques

The key to understanding multivariate statistics is related to the kind of problems each technique is suited for, the objectives of each technique, the data structure required for each technique, and the underlying mathematical model of each technique. In order to understand multivariate analysis, it is important to understand the basic multivariate statistical concepts we described in the previous section. In the following, we will attempt to give a basic description of the main parametric multivariate methods, with the aim of providing a way to choose between them, according to the objective of the analysis and data structure. Many of the methods introduced in the following were already described and addressed in other articles of this book.

Data Quality Assessment

Before deciding on an analysis technique, it is important to have a clear understanding of the best distributional assumption, and of the quality of the data. Estimation of skewness, and kurtosis are helpful in examining the distribution. Nevertheless it is important to understand the magnitude of missing values in the observations, and to determine whether to discard them or to use specific methods to estimate the missing observations. Also, a very important data quality measure is represented by *outliers*. It is, indeed, important to determine whether the outliers should be retained in the analysis or removed. The shortcoming of keeping them is that they may cause a distortion to the data. The advantage of eliminating outliers is that they might support the assumptions of a specific distribution, e.g., normality. Although it is crucial to understand what the outliers represent.

Multiple Regression Analysis

Multiple regression examines the relationship between a single dependent variable, and two or more independent variables. It is the most commonly utilised multivariate technique and is often used as a forecasting tool. Multiple regression analysis aims to determine the linear relationship that minimises the sum of squared variances. As a consequence, the assumptions of normality, linearity, and equal variance are crucial. This method implies the estimation of model coefficients (called weights) that represent the marginal impacts of each variable.

Logistic Regression Analysis

This technique is a variation of multiple regression that allows for the prediction of an event. It is sometimes referred to as *choice model*. This method's objective is to make a probabilistic assessment of a binary choice and hence it utilises (typically) binary dependent variables. The independent variables can be either discrete or continuous. The outcome of this analysis can be provided in terms of a contingency table. This will show the classification of observations as matching or not matching the predicted events. As a measure of the effectiveness of this model we can take the sum of events that were predicted to occur and which actually did occur (true positives) and the events that were predicted to not occur which actually did not occur (false negatives), divided by the total number of events. This measure helps predicting, for example the choices consumers might make when presented with alternatives.

Linear and Quadratic Discriminant Analysis

The purpose of discriminant analysis is to correctly classify observations or subjects into homogeneous groups. In the parametric approach, the independent variables must have a high degree of normality. Discriminant analysis builds a linear discriminant function in which normal variates are assumed to have unequal mean and equal variance. If normal variates are assumed to have unequal mean and unequal variance, the discriminant function is constructed to be quadratic. The discriminant function can then be used to classify the observations. The overall fit is assessed by looking at the degree to which the group means differ, and how well the model classifies. To determine which variables have the most impact on the discriminant function, it is possible to look at F values. The higher the F , the more impact that variable has on the discriminant function. This helps categorize (i.e., discriminate) subjects, between different homogeneous groups (e.g., mice that respond to a drug, mice that do not respond to a drug).

Multivariate Analysis of Variance

It is well known that analysis of variance (ANOVA) assesses the differences between groups (by using T tests for two means, and F tests between three or more means). Similarly, in the case of a multivariate dataset, Multivariate Analysis of Variance (MANOVA) examines the dependence relationship between a set of dependent measures across a set of groups. More explicitly, this technique examines the relationship between several categorical independent variables, and two or more dependent variables. Typically MANOVA is based on a specific hypothesis of relationship between dependent measures, and is often used to validate experimental designs. The null hypothesis is of no difference between categories (e.g., different treatments). In this technique the independent variables are categorical and the dependent variable is not. A limitation of this method is sample size, usually needing 15–20 observations needed per cell. However, too many observations per cell (over 30) often cause overfitting, and cell sizes also should be roughly equal. This is due to the normality assumption of the dependent variables. The model fit is determined by examining the mean vector across groups. If there is a significant difference in the means, the null hypothesis can be rejected and treatment differences can be determined.

Factor Analysis

Factor Analysis (FA) is an independence technique, in which there is no dependent variable. The motivation of FA relies on the fact that often there are many variables involved in a research design, and it is usually helpful to reduce the variables to a smaller set of factors, aiming mainly to understand the underlying structure of the data matrix. The relationship of each variable to the underlying factor is expressed by the so-called factor loading. Again, in the parametric approach, the independent variables are usually assumed to be normal and continuous, with at least three to five variables loading onto a factor. The sample size should be large (i.e., the number of observations should be greater than 50), with at least five observations per variable.

We can broadly define two main factor analysis methods: principal component analysis, which extracts factors based on the total variance of the factors, and common factor analysis, which instead extracts factors based on the variance shared by the factors. Principal component analysis is used to find the fewest number of variables that explain the most variance, whereas common factor analysis is used to look for the latent underlying factors. Usually the first factor extracted explains most of the variance. The factor loadings express the correlations between the variables and the factor. As rule of the thumb, a factor loading of at least 0.4 strongly suggests that a specific variable can be attributed to a factor.

Cluster Analysis

Cluster analysis of a multivariate dataset aims to partition a large data set into meaningful subgroups of subjects. Based on a similarity measure between different subjects, data are divided according to a set of specified characteristics. In this case, outliers also play a pivotal role. The problem of outliers is often caused by variables that might be irrelevant. Moreover it is desirable that the sample under study provide a good representation of the underlying population, and that the variables are uncorrelated.

Clustering methods can be: *hierarchical*, meaning that are based on a tree approach and more appropriate for smaller data sets; *non-hierarchical*, having the shortcoming of requiring the user to specify a priori the number of clusters. Different algorithms are based on specific notion of a cluster, with specific properties. Typical cluster models include: connectivity models, centroid models, distribution models, density models, subspace models, group models, graph-based models and neural models.

Conclusions

In this article we have described the main features of parametric statistics. Then we provided the basics of multivariate statistics, and finally we described briefly a few main multivariate techniques. In particular, we focused on the specific type of research question each method is best suited. It is important to figure out the main strengths and weaknesses of each multivariate technique before trying to interpret any results of its application. Current statistical packages (e.g., in the *R* programming language and *Matlab*) allow one to use built-in procedures features the state of the art of multivariate statistical methods, but the results can be disastrously misinterpreted without adequate care.

Stochastic Processes

Introduction

Stochasticity plays a lead role in biological modelling: from the earliest models applying branching processes to genealogical questions to birth-and-death processes in population dynamics and, more recently, to simulation of stochastic networks in systems biology, stochastic phenomena have always been central (Schuster, 2016). Nowadays, many processes in genetics, epigenetics and cellular metabolism are ruled and controlled by small numbers of molecules. At such extremely low concentrations the deterministic approach fails to capture the discrete and stochastic nature of chemical kinetics. In such a context, noise is increasingly seen as a force shaping biology (Bressloff, 2014). Just to cite a few examples, noise-induced transitions affect stochastic ion channels; molecular motors exploit thermal noise to realize fluctuation-driven transport; the numerous amount of protein-protein interactions (PPIs) causes noise in biochemical signaling; noise can cause genes to express differently. Stochasticity in gene expression can have strong consequences on cell behaviour and function, and its potential advantages are also to be considered. For example, intrinsic noise can provide the flexibility needed by cells to adapt to fluctuating environments or respond to sudden stresses and can also support a mechanism by which population heterogeneity is established during cell differentiation and development. Similarly, in biochemical signaling the promiscuity of PPIs that create signal noise may help the recovery of cell functions through homologous pathways. This signaling noise may also be important for increasing robustness of signaling between cells by dampening incorrect events.

Stochastic aspects of cellular function are hence crucial. The rapid advance in experimental techniques for imaging and probing cells at the molecular level (Single Particle Tracking), as well as the advances in single-molecule techniques for measuring the force-dependent dynamics of molecular motors, DNA, and other macromolecules vital for cell function, stimulated a constantly growing interest in stochastic modelling (Ullah and Wolkenhauer, 2011; Wilkinson, 2012). However, it is worth noting that almost all stochastic models in science assume the so-called Markov property: full knowledge of the present state of the system allows prediction of the future (or of the past). For example, a simple two-state continuous-time Markov process can be used to model the opening and closing of an ion channel, or the binding and unbinding of a ligand molecule to a protein receptor.

Aim of this contribution will be a clear and concise introduction to the topic; we will not adopt the mathematically oriented exposition or the measure-theoretic framework of many classical textbooks (e.g., Karlin and Taylor, 1975) to whom we refer for further reading. Following the approach of many basic and intermediate textbooks (Cox and Miller, 2001; Gardiner, 2004; Van Kampen, 2007; Sheldon, 2009; Stirzaker, 2005), we present the theory essentially restricting ourselves to Markov processes; applications to biology are outlined where possible, also through a wide review of the recent literature on stochastic modelling. Finally, numerical simulation of stochastic processes is faced, by description of the simplest and most popular algorithms and also by reference to more advanced techniques.

Fundamentals

Loosely speaking, a stochastic process is the mathematical representation of a system which evolves probabilistically. Then, it is a collection of random variables $\{X(t), t \in T\}$, where both the index t and the random variable X can be discrete or continuous. In the following, for simplicity we generally refer to t as time, even if it can be useful to consider stochastic processes in different formal spaces, such as the genotype or sequence space. There, the points represent individual genotypes and the distance between genotypes counts the minimal number of point mutations required to bridge the interval between them. Neutral evolution and Darwinian selection, for example, can be visualized as processes in genotype space (Ewens, 1979).

A listing of the values assumed by the random variable at specific times, i.e., a sequence of time-ordered pairs (x, t) , is called a *trajectory* or a *sample path* of the process. If the set T is countable (finite or enumerable), we call X a discrete-time process; if, on the contrary, T is (an interval of) the real axis, X is called a continuous-time process. The set of possible values X , called the *state space* of the process, can be uni- or multidimensional; moreover, it can be discrete or continuous.

The complete specification of a process requires knowledge of the joint distributions (or the joint densities, if they exist) of the random variables $X_1, \dots, X_k$ for any k ; in the following we assume that the finite joint probability densities $p(x_1, t_1; \dots; x_n, t_n)$ exist for any n . Note that, in such a notation, we have not yet assumed anything about the ordering of the random variables. The marginalization of the joint density over one of the random variables gives the so-called Chapman-Kolmogorov Equation:

$$p(x_1, t_1; \dots; x_{n-1}, t_{n-1}) = \int p(x_1, t_1; \dots; x_n, t_n) dx_n \quad (1)$$

obviously, for discrete variables, the integral in Eq. (1) is replaced by a sum.

Model equations for stochastic processes can be grouped in two classes: the first group deals with the representation of the trajectories of the process, given by the random variable $X(t)$. Mathematically speaking, these trajectories are described by

stochastic differential equations (SDE), that are differential equations in which one or more of the terms are stochastic, so that the solution itself is a stochastic process. The second group describes the evolution of the probability $p(x, t) = \text{Prob}[X(t)=x]$ by means of deterministic differential equations, such as the Chapman-Kolmogorov Equation in its differential form and the derived ones (Fokker-Planck, Chemical Master Equation,...).

Some Definitions

Let us introduce the main properties characterizing some classes of stochastic processes that will be useful in the applications.

Independence

The simplest class of stochastic processes is characterized by complete independence of events: $X(t)$ does not depend on any of the $X(s)$ for $s < t$. Then the joint density fully factorizes:

$$p(x_1, t_1; \dots; x_n, t_n) = p(x_1, t_1)p(x_2, t_2) \dots p(x_n, t_n)$$

Markov

The Markov property assumes that prediction of the future requires knowledge of the present alone. In other terms, a stochastic process is a Markov process if for arbitrary times $t_1 < t_2 < \dots < t_n$ the conditional probability reduces to a transition probability between the last two states:

$$p(x_n, t_n | x_1, t_1; \dots; x_{n-1}, t_{n-1}) = p(x_n, t_n | x_{n-1}, t_{n-1}) \quad (2)$$

Then, any joint probability density can be expressed as the product of transition probabilities and an initial probability:

$$p(x_1, t_1; x_2, t_2; \dots; x_n, t_n) = p(x_n, t_n | x_{n-1}, t_{n-1}) \dots p(x_2, t_2 | x_1, t_1) p(x_1, t_1) \quad (3)$$

Stationarity

A stochastic process is said to be *strictly* or *strongly* stationary if the joint probability densities are invariant under time translations:

$$p(x_1, t_1; x_2, t_2; \dots; x_n, t_n) = p(x_1, t_1 + \Delta t; x_2, t_2 + \Delta t; \dots; x_n, t_n + \Delta t)$$

Wide-sense or *weak* stationarity requires instead only the invariance under time translation of the mean and covariance of the process:

$$E[X(t)] = \mu_X(t) = \mu_X(t + \Delta t)$$

$$\text{Cov}[X(t_1), X(t_2)] = C_X(t_1, t_2) = C_X(t_1 - t_2, 0)$$

In this case, the mean of the process is a constant and its covariance only depends on the time difference $t_1 - t_2$.

Continuity

A process is continuous if each of its sample paths is a continuous function of t . For a Markov process, this definition specifies as

$$\forall \varepsilon > 0 \quad \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} \int_{|x-z| > \varepsilon} p(x, t + \Delta t | z, t) dx = 0$$

uniformly in z , t and Δt .

Gaussianity

A process is Gaussian if every finite joint density is a multivariate Gaussian. Then the process is completely specified by its mean $E[X(t)]$ and covariance $E[X(t), X(s)]$ functions.

Markov Processes

Mathematical models generally make simplifying assumptions about properties of the phenomena being modelled. Such modelling assumptions often do not hold exactly; however they frequently allow a good compromise between accuracy and tractability of models. The common assumption when applying stochastic processes to modelling is the Markov property; thus, in the following, we restrict our attention to Markov processes. Methods for dealing with non-Markov processes, generally by their embedding in suitable Markov processes, can be found in classical textbooks (e.g., [Cox and Miller, 2001](#)).

When the stochastic process under consideration is Markov, the Chapman-Kolmogorov [Eq. \(1\)](#) is equivalent to an identity on the transition probability densities:

$$p(x_3, t_3 | x_1, t_1) = \int p(x_3, t_3 | x_2, t_2) p(x_2, t_2 | x_1, t_1) dx_2 \quad (4)$$

informally, this says that the probability of a transition from x_1 to x_3 can be expressed by adding up the probabilities of transitions from x_1 to any possible intermediate state x_2 and then from x_2 to x_3 . Note that the integral notation in [Eq. \(4\)](#) has to be intended wide-sense: it represents an integral only for continuous processes under suitable regularity hypotheses. For processes with discrete

state space it will be replaced by a summation while for discontinuous processes the notation will include both integration on continuity intervals and summation on single discontinuity points.

In any case, we can obtain from Eq. (4) differential equations for the transition probabilities. To simplify the notation, we assume fixed and sharp initial conditions (x_0, t_0) so that the unconditioned probability of the state (x, t) is the same as the probability of the transition from (x_0, t_0) to (x, t) :

$$p(x, t) = p(x, t | x_0, t_0)$$

Then if we replace t_1, t_2, t_3 with $\tau, t - dt, t$ and pass to the limit we obtain the forward equation

$$\frac{\partial}{\partial t} p(x, t) = - \sum_i \frac{\partial}{\partial x_i} (A_i(x, t) p(x, t)) + \frac{1}{2} \sum_{ij} \frac{\partial^2}{\partial x_i \partial x_j} (B_{ij}(x, t) p(x, t)) + \int dz (W(x|z, t) p(z, t) - W(z|x, t) p(x, t)) \quad (5)$$

it is important to notice that the integral sign stands actually for a principal value integral, since the transition probability may approach infinity.

The three terms $A(x, t)$, $B(x, t)$ and $W(x|z, t)$ represent drift, diffusion and transition for discontinuous jumps, respectively; in other words, if $X(t)$ is a continuous process, in the limit $z \rightarrow x$ the expectation value of the increment $X(t + dt) - X(t)$ approaches $A(X(t), t)dt$ and its covariance converges to $B(X(t), t)dt$. Let us consider some specific cases: when $W=0$ we obtain continuous processes, specifically pure drift processes ($B=0$, Liouville equation), pure diffusion processes – Brownian motion ($A=0$, Wiener equation), or drift-diffusion processes ($A \neq 0$ and $B \neq 0$, Fokker-Planck equation). On the contrary, when only $W \neq 0$ the variables x and z evolve in jumps and the process is described by a so-called master equation.

While the Fokker-Planck equation is used with problems where the initial distribution is known, if the problem is to know the distribution at previous times, the Kolmogorov backward equation can be used:

$$\frac{\partial}{\partial t} p(x_0, t_0 | x, t) = - \sum_i A_i(x, t) \frac{\partial p(x_0, t_0 | x, t)}{\partial x_i} - \frac{1}{2} \sum_{ij} B_{ij}(x, t) \frac{\partial^2 p(x_0, t_0 | x, t)}{\partial x_i \partial x_j} \quad (6)$$

here the final condition (x, t) is given while the initial state and time (x_0, t_0) are variable and integration is performed backward in time. Such a formulation is particularly useful in problems involving *hitting times* or *escape times*, since the time to reach a specific target (or to leave a specific region), the so-called First Passage Time, FPT, is a random variable whose probability density satisfies a Kolmogorov backward equation.

Finally, a number of important cellular processes at the macromolecular level involve a coupling between continuous external variables and discrete internal variables, and this coupling is modelled using a stochastic hybrid system (Bressloff, 2014; Wilkinson, 2012). Consider, for example, molecular motors, that undergo a cyclic sequence of conformational changes after reacting with one or more molecules of a chemical such as ATP, resulting in the release of chemical energy; another example is given by voltage-gated or ligand-gated ion channels, in which the opening and closing of the channel depend on an external variable such as membrane voltage or calcium concentration.

Main Markov Processes

Let us introduce now, by some examples, the main Markov processes and some of their applications.

Markov chains

A Markov chain is a process that occurs in a series of time-steps in each of which a random choice is made among a finite (or also enumerable) number of states; since both the index set and the state space are discrete, we denote by $X_n = X(t_n)$; the transition probability can then be represented by a matrix $P = (p_{ij})$, where p_{ij} is the probability of moving from state i to state j : $p_{ij} = \text{Prob}[X_{n+1} = j | X_n = i]$. For homogeneous chains, these probabilities do not depend on t , i.e., they are stationary. Then, the initial distribution, together with the transition matrix P , determines the probability distribution for any state at all future times.

All the elements of the matrix P are non-negative and its row sums are unity; such matrices are called stochastic matrices. Now, the states of a Markov chain are *recurrent*, if the probability of eventual return to that state is 1, or *transient*, otherwise. State types and properties of the chain are related to properties of the stochastic matrix (Cox and Miller, 2001).

The classical model of enzyme activity, Michaelis-Menten kinetics, can be viewed as a Markov chain, where at each time step the reaction proceeds in some direction (Ingalls, 2013). Markov chains also have many applications in biological modelling, particularly for population growth processes or epidemics models (Allen, 2010). Branching processes are other examples. These chains have been used in population genetics to model variety-increasing processes such as mutation as well as variety-reducing effects such as genetic drift and natural selection. Markov chains take part in the modelling of hybrid stochastic systems (Ullah and Wolkenhauer, 2011; Wilkinson, 2012). Finally, they are the basis for Markov chain Monte Carlo (MCMC) methods, a class of algorithms for sampling from a probability distribution based on constructing a Markov chain that has the desired distribution as its equilibrium distribution.

The Poisson process

We consider point events occurring randomly in time and, denoting by $N(t, t + \Delta t)$ the number of events in $(t, t + \Delta t]$, we assume that there is a positive constant ρ (rate of occurrence) such that, as $\Delta t \rightarrow 0$,

$$\text{Prob}[N(t, t + \Delta t) = 0] = 1 - \rho\Delta t + o(\Delta t)$$

$$\text{Prob}[N(t, t + \Delta t) = 1] = \rho\Delta t + o(\Delta t)$$

where, as usual, $o(\Delta t)$ denotes a general and unspecified remainder term of smaller order than Δt . Moreover, we assume that $N(t, t + \Delta t)$ is independent of occurrences in $(0, t]$. In such a process, the number of events in any interval of length Δt has a Poisson distribution of mean $\rho\Delta t$:

$$\text{Prob}[N(t, t + \Delta t) = k] = \frac{(\rho\Delta t)^k e^{-\rho\Delta t}}{k!} \quad k = 0, 1, \dots$$

while the intervals between successive events are independent and exponentially distributed. Evolutionary models in continuous time (Ewens and Grant, 2005; cap. Kloeden and Platen, 1992) use Poisson processes; the activity of nerve cells and neuron firing in LIF model are described by Poisson processes (Tuckwell, 1989). Generalizations of the Poisson process, allowing the rate ρ to vary with time, or also to depend on the number of events already occurred, for example, leads to pure-birth processes; to epidemic models (Allen, 2010).

Brownian motion

The most important continuous time stochastic process is Brownian motion. It originated in physics as a description for the motion of small particles immersed in a fluid. Today, along with its many generalizations and extensions, it occurs in numerous and diverse areas of pure and applied science. Brownian motion is a mean zero, continuous process in both time and state space with independent Gaussian increments. Then, $W(t)$ is a Brownian motion (or a Wiener process) with diffusion coefficient σ^2 if:

1. $W(0) = 0$;
2. $W(t)$ has independent, stationary increments; and
3. for every t , $W(t)$ is normally distributed with zero mean and variance $\sigma^2 t$.

Then, an initially sharp distribution spreads in time: individual trajectories are extremely variable and diverge after short times. A simple generalization is the process with drift, where the increments in a small interval dt have mean μdt and variance $\sigma^2 dt$. The probability density of the Wiener process is the solution of the Fokker-Planck Eq. (5), that in this case reads

$$\frac{\partial p(x, t)}{\partial t} = \frac{1}{2} \sigma^2 \frac{\partial^2 p(x, t)}{\partial x^2}$$

Passive, as well as facilitated diffusion in cells can be modelled by an overdamped Brownian motion; the theory of Brownian ratchets is based on Brownian particles moving in a periodic ratchet (asymmetric) potential (Bressloff, 2014, for both).

Methodologies for Numerical Investigation

Numerical investigation on a stochastic process can involve Monte Carlo simulation of the trajectories to obtain approximate solutions of the process SDE; alternatively, the probability distribution function of the process as a function of time can be obtained by solving the related equations (Fokker-Planck Equation (Eq. (5)), Chemical Master Equation, CME (Eq. (6)). Let us briefly describe some tools for both approaches.

Methods for SDEs

In physical science, SDEs are usually written as Langevin equations. Those forms consist of an ordinary differential equation containing a deterministic function and an additional term which represents random white noise calculated as the derivative of Brownian motion or the Wiener process:

$$dX(t) = a(X(t))dt + b(X(t))dW(t) \quad (7)$$

However, other types of random behaviour are possible, such as jump processes.

Numerical solution of SDEs is a quite young field; algorithms developed for the solution of ODEs can be generalized but usually they work very poorly for SDEs. We describe here the simplest time-discrete approximation, the Euler-Maruyama method that is the stochastic generalization of Euler method for ODEs. A good reference text for other and more sophisticated algorithms is Kloeden and Platen (1992).

Consider the stochastic differential Eq. (8) with initial condition $X(0) = x_0$, and suppose that we wish to solve this SDE on some time interval $[0, T]$. Then the Euler-Maruyama approximation to the true solution $X(t)$ is the Markov chain Y defined as follows:

1. partition the interval $[0, T]$ into N equal subintervals of width $\Delta t > 0$: $0 = \tau_0 < \tau_1 < \dots < \tau_N = T$ and $\Delta t = T/N$;

2. set $Y(0)=x_0$; and
3. recursively define Y_n for $1 \leq n \leq N$ by $Y_{n+1}=Y_n+a(Y_n)\Delta t+b(Y_n)\Delta W_n$, where $\Delta W_n=W_{\tau_{n+1}}-W_{\tau_n}$.

The random variables ΔW_n are independent and identically distributed normal random variables with expected value zero and variance Δt . In simulations, to construct Y_n we only need to generate realizations of such random variables via a pseudo-random number generator at any timestep. Note that, with similar procedures (Sheldon, 2009; cap. Ingalls, 2013), it is also possible to simulate random variables having a different (non Gaussian) distribution, when the adopted model assumes correlated, or “colored”, noise instead of white noise.

Simulation of Reacting Systems

The Stochastic Simulation Algorithm (SSA) proposed by Gillespie (1977) is a numerical procedure for the exact simulation of the time evolution of a reacting system. In the limit of large number of reactants it converges (as the CME) to the deterministic solution of the law of mass action. Now, while traditional continuous and deterministic biochemical rate equations, typically modelled as a set of coupled ordinary differential equations, rely on bulk reactions that require the interactions of millions of molecules, the Gillespie algorithm allows a discrete and stochastic simulation of a system with few reactants because every reaction is explicitly simulated. The physical basis of the algorithm is the collision of molecules within a reaction vessel. It is assumed that collisions are frequent, but collisions with the proper orientation and energy are infrequent. Therefore, all reactions within the Gillespie framework must involve at most two molecules. Reactions involving three molecules are assumed to be extremely rare and are modelled as a sequence of binary reactions. It is also assumed that the reaction environment is well mixed.

The algorithm, in its original version, proceeds through these steps: Set the initial values for the number of molecules in the system, the reaction constants, and the random number generators. Then repeat the following two steps until the number of reactants is zero or the simulation time has been exceeded:

1. Two independent random numbers are generated to determine which reaction will take place as well as the time interval to this occurrence. The probability of a given reaction to be chosen depends on the different rate constants and population size of the chemical species.
2. The current time is updated by the randomly generated time and so is the molecule count based on the reaction that occurred.

The algorithm is computationally expensive and thus many modifications and adaptations exist, including the Next Reaction Method (Gibson and Bruck, 2000), more efficient both in terms of number of operations and number of random numbers used; the tau-leaping (Daniel, 2001), performing all reactions for an interval of length tau before updating the propensity functions; hybrid stochastic-deterministic techniques have also been proposed (see Wilkinson (2012) and references therein), where abundant reactants are modelled with deterministic behaviour. Another alternative to the SSA is the Stochastic Simulation algorithm (StochSim) (Le Novère and Shimizu, 2001; Morton-Firth and Bray, 1998), where time is quantized in intervals whose size depends on the most rapid reaction in the system. Then in each interval one or two objects (species or pseudo-species) are selected at random and the corresponding reaction will occur or not according to probabilities given in the look-up tables.

Future Directions/Closing Remarks

Stochastic processes and biological/biochemical modelling are increasingly merging in recent years as technology has started giving real insight into intra-cellular processes: quantitative real-time imaging of expression at the single-cell level and improvement in computing technology are allowing modelling and stochastic simulation of such systems at levels of detail previously impossible. “The message that keeps being repeated is that the kinetics of biological processes at the intra-cellular level are stochastic, and that cellular function cannot be properly understood without building that stochasticity into *in silico* models” (Wilkinson, 2012, Preface). The relevance of noise and stochastic modelling to state-of-the-art molecular and cell biology is thus unquestionable. Just to cite a few advanced topics that are currently considered: models of passive and active transport in cells; models of self-organization of cytoskeletal structures; models for the interplay between diffusion and nonlinear chemical reactions.

Understanding and modelling of biological noise, that plays an important role in cell fate decisions, environmental sensing and cell-cell communication, is another issue of main interest, as reported by Eldar and Elowitz in a recent review (Eldar and Elowitz, 2010).

Hidden Markov Models

© 2019 Elsevier Inc. All rights reserved.

Introduction

Hidden Markov models (HMMs), named after the Russian mathematician Andrey Andreyevich Markov, who developed much of relevant statistical theory, are introduced and studied in the early 1970s. They were first used in speech recognition and have been successfully applied to the analysis of biological sequences since late 1980s. Nowadays, they are considered as a specific form of dynamic Bayesian networks, which are based on the theory of Bayes. HMMs are statistical models to capture hidden information from observable sequential symbols (e.g., a nucleotidic sequence). They have many applications in sequence analysis, in particular to predict exons and introns in genomic DNA, identify functional motifs (domains) in proteins (profile HMM), align two sequences (pair HMM). In a HMM, the system being modelled is assumed to be a Markov process with unknown parameters, and the challenge is to determine the hidden parameters from the observable parameters. A good HMM accurately models the real world source of the observed real data and has the ability to simulate the source. A lot of Machine Learning techniques are based on HMMs have been successfully applied to problems including speech recognition, optical character recognition, computational biology and they have become a fundamental tool in bioinformatics: for their robust statistical foundation, conceptual simplicity and malleability, they are adapted fit diverse classification problems. In Computational Biology, a hidden Markov model (HMM) is a statistical approach that is frequently used for modelling biological sequences. In applying it, a sequence is modelled as an output of a discrete stochastic process, which progresses through a series of states that are 'hidden' from the observer. Each such hidden state emits a symbol representing an elementary unit of the modelled data, for example, in case of a protein sequence, an amino acid. In the following sections, we first introduce the concepts of Hidden Markov Model as a particular type of probabilistic model in a Bayesian framework; then, we describe some important aspects of modelling Hidden Markov Models in order to solve real problems, giving particular emphasis in its use in biological context. To show the potentiality of these statistical approaches, we present the stochastic modelling of an HMM, defining first the model architecture and then the learning and operating algorithms. In this work we illustrate, as example, applications in computational biology and bioinformatics and, in particular, the attention is on the problem to find regions of DNA that are methylated or un-methylated (CpG-islands finding).

Stochastic Process

The basic idea of the process modelling is to construct a model of a process starting from a set of sequences of events typically generated by the process itself. Subsequently, the model could be also used to discover properties of the process, or to predict future events on the basis of the past history. From a general point of view, a model can be used for three main purposes: describing the details of a process, predicting its outcomes, or for classification purposes, i.e., predicting a single variable k , which takes values in a finite unordered set, given some input data $x = (x_1, \dots, x_n)$. Against the deterministic model, which predicts outcomes with certainty, with a set of equations that describe the system inputs and outputs exactly, a stochastic model represents a situation where uncertainty is present. In other words, it's a model for a process that has some kind of randomness. The word "stochastic" derives from the Greek and means *random* or *chance*. A deterministic model predicts a single outcome from a given set of circumstances. A stochastic process is a sequence of events, in which the outcome at any stage depends on some probabilities. It means that a stochastic model predicts a set of possible outcomes weighted by their likelihoods, or probabilities. In modelling stochastic processes the key role is played by time; in fact, the stochastic model is a tool for predicting probability distributions of potential outcomes by allowing a random variation in its inputs over time. A stochastic process is defined as a collection of random variables $X = \{X_t; t \in T\}$ defined on a common probability space, taking values in a common set S (the *state space*), and indexed by a set T , often either $\mathbb{N}$ or $[0, \infty)$ and thought of as *time* (discrete or continuous respectively) (Oliver, 2009).

Markov Processes and Markov Chains

Important classes of stochastic processes are Markov processes and Markov chains. A Markov process is a process that satisfies the Markov property (*memoryless*), i.e., it does not have any memory: the distribution of the next state (or observation) depends exclusively on the current state. Formally, a stochastic process $X(t)$ is a Markov process, if it has the following properties:

1. The number of possible outcomes or states is finite.
2. The probabilities are constant over time.
3. It satisfies *memoryless* property.

$$P\{X(t_{n+1}) = x_{n+1} | X(t_n) = x_n, \dots, X(t_1) = x_1\} = P\{X(t_{n+1}) = x_{n+1} | X(t_n) = x_n\}$$

for any choice of time instants t_i , con $i = 1, \dots, n$ where $t_j > t_k$ for $j > k$.

Markov chain is a specific Markov process with a finite or countable state-space. Considering a set of states, $S = \{s_1, \dots, s_r\}$, we describe Markov chain as a process that starts in one of these states and moves successively from one state to another. Each move is called *step*. If the chain is currently in state s_i , then it moves to state s_j at the next step with a probability denoted by p_{ij} ; this probability does not depend upon which states the chain was in before the current state. The probabilities p_{ij} are called transition probabilities and are defined as the probabilities that the Markov chain is at the next time point in state j , given that it is at the present time point at state i . The matrix P with elements p_{ij} is called the transition probability matrix of the Markov chain. Since the state space is countable (or even finite), we can use the integers Z or a subset such as Z_+ (non-negative integers), the natural numbers $N = \{1, 2, 3, \dots\}$ or $\{0, 1, 2, \dots, m\}$ as the state space. We refer to Markov chains as *time homogeneous* or having stationary transition probabilities. Then, the probability of the transition from i to j between time point n and $n + 1$ is given by conditional probability function $P(X_{n+1} = j | X_n = i)$. We will assume that the transition probabilities are the same for all time points so that there is no time index needed on the left hand side. Given that the process X_n is in a certain state, the corresponding row of the transition matrix contains the distribution of X_{n+1} , implying that the sum of the probabilities over all possible states equals one. The transition probability matrix (see Table 1) contains a conditional discrete probability distribution on each of its rows. Formally,

$$p_{ij} \geq 0, \forall i, j \in S$$

$$\sum_{j \in S} p_{ij} = 1, \forall i \in S$$

In general, we define Markov chain as k th-order Markov model, when the probability of X_{j+k} conditioned on all previous elements in the sequence is identical to the probability of X_{j+k} conditioned on the previous k elements only:

$$P(X_{j+k} | X_1, \dots, X_j) = P(X_{j+k} | X_{j+k-1}, \dots, X_j)$$

In particular, in zeroth-order Markov chain $k=0$. It means that the variables X_i are independent, i.e., $P(X_j | X_1, \dots, X_{j-1}) = P(X_j)$.

It is always possible to represent a time-homogeneous Markov chain by a transition graph. Then, any transition probability matrix P (see Table 1) can be visualized by a transition graph, where the circles are nodes and represent possible states s_i , while edges between nodes are the transition probabilities p_{ij} (see Fig. 1).

Markov chains are probabilistic models, which can be used for the modelling of sequences given a probability distribution and then, they are also very useful for the characterization of certain parts of a DNA or protein string given, for example, a bias towards the AT or GC content. DNA sequences consist of one of four possible bases $\{A, T, C, G\}$ at each position. Each sequence is always read in a specific direction, from the 5' to the 3' end. Each place in the sequence can be thought of as a state space, which has four

possible states $\{A, T, C, G\}$, where each state of the nucleotide is sequentially dependent on the nucleotide adjacent and immediately upstream of it, and only that nucleotide. Each position in the sequence can be represented with a random variable $X_0, X_1, \dots, X_n$ that takes a value of one of the states in the state space for a particular place in the sequence. In a Markov Chain of zero order, the current state (or nucleotide) is totally independent of the previous state, so it's no memory and every state is untied. For the first order Markov Chain the case is different, because the current state actually depends only on the previous state. In the **Fig. 2** a first-order Markov chain is shown: the sequence goes in the 5' to 3' direction and $X_0=A, X_1=T$ and so forth. In this case, we can express the probability of this sequence using the Markov Property as follows:

$$P(X_5 = C | X_4 = C, X_3 = G, X_2 = T, X_1 = T, X_0 = A) = P(X_5 = C | X_4 = C)$$

and its transition probability matrix is shown in **Table 2**.

Hidden Markov Model

Now, we can define the Hidden Markov Models as probabilistic models, in which sequences are generated from two coexistent stochastic processes: the process of moving between states and the process of emitting an output sequence, characterized by Markov property and the output independence. The first one is a Markov model represents by a finite set of states, which generates the sequence of states of variables, specified by the initial state probabilities and state transition probabilities between variables; the second is characterized by the emission of one character of a given alphabet from each state, with a probability distribution that only depends from the state. The sequence of state transitions is a hidden process; it means that the variable states cannot be directly observed but they are observed through the sequences of emitted symbols, therefore the name *Hidden Markov Model*. Then, an Hidden Markov Model is defined by states, state probabilities, transition probabilities, emission probabilities and initial probabilities. They constitute the architecture of an HMM. Formalizing the definition, an HMM is a quintuple (S, V, π, A, B) , characterized by the following elements (Rabiner and Juang, 1986a):

- $S = \{S_1, \dots, S_N\}$ is the set of *states*, where N is the number of states. The triplet (S, π, A) represents a Markov chain; the states are hidden and we never observe them directly.
- $V = \{v_1, \dots, v_M\}$ is the *vocabulary*, the set of symbols that may be emitted.
- $\pi: S \rightarrow [0,1] = \{\pi_1, \dots, \pi_N\}$ is the *initial probability distribution* on the states. It gives the probability of starting in each state. We expect that

$$\sum_{s \in S} \pi(s) = \sum_{i=1}^N \pi_i = 1$$

- $A = (a_{ij})_{i \in S, j \in S}$ is the *transition probability* of moving from state S_i to state S_j . We expect that $a_{ij} \in [0,1]$ for each S_i and S_j , and that $\sum_{j \in S} a_{ij} = 1$, for each S_i .
- $B = (b_{ij})_{i \in V, j \in S}$ is the *emission probability* that symbol v_i is seen when we are in state S_i .

HMMs provide great help when there is the need of modelling a process in which there is not a direct knowledge about the state in which the system is. The key idea is that an HMM is a sequence “generator”. In general, we talk about emission of

observable events because we can think of HMMs as generative models that can be used to generate observation sequences. Algorithmically, a sequence of observations $O = o_1, \dots, o_T$, with $o_t \in V$ can be generated by an HMM, described by the algorithm in [Fig. 3](#) ([Rabiner and Juang, 1986a](#)). Two assumptions are made by the model. The first is called the Markov assumption and represents the memory of the model; it means that the current state is dependent only on the previous state; formally:

$$P(q_t | q_1^{t-1}) = P(q_t | q_{t-1})$$

The second is the independence assumption, i.e., the output observation at time t is dependent only on the current state and it is independent of previous observations and states:

$$P(o_t | o_1^{t-1}, q_1^t) = P(o_t | q_t)$$

A simple HMM for generating a DNA sequence is specified in [Fig. 4](#). In this model, state transitions and their associated probabilities are indicated by arrows; and symbol emission probabilities for A, C, G, T at each state are indicated below the state. For clarity, we omit the initial and final states as well as the initial probability distribution. For instance, this model can generate the state sequence given in [Fig. 5](#) and each state emits a nucleotide according to the emission probability distribution. The logical idea of an HMM suggests the potential ability of this approach for modelling problems in computational biology. In particular, [Baldi and Brunak \(1998a\)](#) define three main groups of problems in computational biology for which HMMs have been useful. The first problem is the multiple alignments of DNA sequences, which is more difficult using a dynamic programming approach. The second is to discover periodic sequences within specific regions of biological data from the knowledge of consensus patterns. The third is the problem to classify each nucleotide according to which structure it belongs. HMMs have also been used in protein

Statistical Inference in Hidden Markov Models

Once the architecture of an HMM has been decided, to analyze and describe data in almost all applications of HMMs, three distinct questions must to be solved:

1. What is the probability of an observed sequence according to a given HMM?
2. How to find the optimal state sequence that the HMM would use to generate the observed sequence?
3. How to find the structure and parameters of the HMM that best accounts for the data?

In general, in order to use the HMMs in application contexts, for example, in computational biology, to solve these questions, we need to be able to:

- 1) *Evaluate* the likelihood of the model given the observations, i.e., to compute the probability of the observation sequence for a model.
- 2) *Decode* the most likely state sequence given the observations, i.e., to find the optimal corresponding state sequence given the observation sequence and the model.
- 3) *Learning or training* to estimate the model parameters (initial probabilities, transition probabilities, and emission probabilities), that best explains the observation sequences given the model structure, describing the relationships between variables.

Evaluation Problem

Given a sequence of observations and an HMM, to solve the first problem, we would like to be able to compute the probability (or likelihood), $P(O|\lambda)$, that the observed sequence is produced by the model. This problem could be viewed as one of evaluating how well a model predicts a given observation sequence and thus allow us to choose the most appropriate model from a set. For this purpose, the forward-backward algorithm and the result can be used (Rabiner and Juang, 1986a; Stratonovich, 1960a). We consider the probability of the observations O for a specific state sequence Q

$$P(O|Q, \lambda) = \prod_{t=1}^T P(o_t|q_t, \lambda) = b_{q_1}(o_1) \times b_{q_2}(o_2) \dots b_{q_T}(o_T)$$

and the probability of the state sequence

$$P(Q|\lambda) = \pi_{q_1} a_{q_1 q_2} a_{q_2 q_3} \dots a_{q_{T-1} q_T}$$

The join probability that O and Q occur simultaneously is simply the product of above two terms $P(O|Q, \lambda) P(Q|\lambda)$. Then, we can obtain the probability of the observations given the model by summing this join probability over all possible state sequences

$$P(O|\lambda) = \sum_Q P(O|Q, \lambda) P(Q|\lambda) = \pi_{q_1} b_{q_1}(o_1) a_{q_1 q_2} b_{q_2}(o_2) \dots a_{q_{T-1} q_T} b_{q_T}(o_T)$$

To evaluate the last equation the forward-backward approach, that reduced complexity, is used. The key idea is to process a sequence, consider a forward or backward loop that processes it one element at a time. The sequence $X(1 \dots T)$ is broken into two parts, a "past" sequence $X(1 \dots t)$ and a "future" sequence $X(t+1 \dots T)$. In the Hidden Markov Model, each symbol emission and each state transition depend only on the current state; there is no memory of what happened before, no lingering effects of the past. This means that we can work on each half separately. Splitting the sequence into two parts, the inductive calculation on t can be used: if t advances from 1 towards T , it is called *forward* calculation, while if t is decremented down from T towards 1, it is called the *backward* calculation. In formal terms, the forward algorithm calculates the probability of being in a state i at time t and having emitted the output $o_1, \dots, o_t$. These probabilities are named the *forward variables*. By calculating the sum over the last set of forward variables, one obtains the probability of the model having emitted the given sequence. Both the forward algorithm and the backward algorithm involve three steps: initialization, recursion (or induction), and termination. We define the forward probability variable α as the probability of the partial observation sequence $o_1, \dots, o_t$ and state s_i at time t :

$$\alpha_t(i) = P(o_1 o_2 \dots o_t, q_t = s_i | \lambda)$$

Fig. 6 The recursion step of the forward algorithm.

The forward algorithm is as follows:

1. *Initialization*

Calculate the forward probability at the first position $\alpha_1(i) = \pi_i b_i(o_1)$, $1 \leq i \leq N$

2. *Recursion*

Compute the forward probability

$$\alpha_{t+1}(j) = \left[\sum_{i=1}^N \alpha_t(i) a_{ij} \right] b_j(o_{t+1}), \quad 1 \leq t \leq T-1, \quad 1 \leq j \leq N$$

The recursion step is the key to the forward algorithm (see Fig. 6). For each state s_i , $\alpha_j(t)$ stores the probability of arriving in that state, having observed the observation sequence up until time t .

3. *Termination*

When $i=N$, the forward recursion stops. Then, the probability of the whole sequence of observations can be found by summing the forward probabilities over all the states at the final variable

$$P(O|\lambda) = \sum_{i=1}^N \alpha_T(i)$$

This approach reduces the complexity of calculations involved to N^2T rather than $2TN^T$. Similarly, backwards algorithm can be defined. It is the exact reverse of the forwards algorithm, with the backwards variable

$$\beta_t(i) = P(o_{t+1}o_{t+2}\dots o_T, q_t = s_i|\lambda)$$

as the probability of the partial observation sequence from $t+1$ to T , starting in state s_i .

Decoding Problem

The aim of decoding is to find the optimal state sequence associated with a given observation sequence. There are several possible ways to solve this problem. One possible optimality solution is proposed by the *Viterbi algorithm* (Viterbi, 1967a). The Viterbi algorithm uses a dynamic programming approach to find the most likely sequence of states Q given an observed sequence O and model λ . It works similarly to the forward algorithm. The goal is to get the most likely path through the HMM for a given observation; then, only the most likely transition from a previous state to the current one is important. Therefore, the transition probabilities are maximized at each step, instead of summed. To implement this solution, we define the variable

$$\delta_t(i) = \max_{q_1, q_2, \dots, q_{t-1}} P(q_1, q_2, \dots, q_t = s_i, o_1, o_2, \dots, o_t|\lambda)$$

It is the probability of the most probable state path for the partial observation sequence. Corresponding to each node, two storage variables are used to cache the probability of the most likely path for the partial sequence of observations and the state at the previous variable to lead this path, denoted $\delta_t(i)$ and $\psi_t(i)$, respectively. The Viterbi algorithm consists of four steps: initialization, recursion, termination, and backtracking. It is described as follows:

1. *Initialization*

Calculate $\delta_1(i) = \pi_i b_i(o_1)$, $1 \leq i \leq N$ and set $\psi_1(i) = 0$

2. *Recursion*

Calculate

$$\delta_t(j) = \max_{1 \leq i \leq N} [\delta_{t-1}(i) a_{ij}] b_j(o_t), \quad 2 \leq t \leq T, \quad 1 \leq j \leq N$$

and record the state

$$\psi_t(j) = \arg \max_{1 \leq i \leq N} [\delta_{t-1}(i) a_{ij}], \quad 2 \leq t \leq T, \quad 1 \leq j \leq N$$

3. Termination

The recursion ends when $i=N$. The probability of the most likely path is found by

$$P^* = \max_{1 \leq i \leq N} [\delta_T(i)]$$

The state of this path at variable N is found by

$$q^* = \arg \max_{1 \leq i \leq N} [\delta_T(i)]$$

4. Backtracing

The last observation frame at time T is needed in order to decode the global optimal state path from T back to the first time index. The state of the optimal path at variable i is found by

$$q_t^* = \psi_{t+1}(q_{t+1}^*), \quad t = T-1, T-2, \dots, 1$$

The backtracking allows the best state sequence to be found from the back pointers stored in the recursion step.

Learning Problem

How can we adjust the HMM parameters in a way that a given set of observations, called *training set*, is represented by the model in the best way for our purposes? Training involves adjusting the transition and output probabilities until the model sufficiently fits the process. These adjustments are performed using techniques to optimize $P(O|\lambda)$, the probability of observed sequence $o_1, \dots, o_T$, given model λ over a set of training sequences. How do we learn the parameters of an HMM from observations? Depending on the application, the “quantity” that should be optimized during the learning process differs. There isn’t known way to analytically solve this problem. Therefore iterative procedures or gradient techniques for optimization can be used. Here we will only present the iterative procedure. Therefore, we can choose an HMM such that $P(O|\lambda)$ is locally maximized. In literature, we can find several optimization criteria for learning. We present an iterative procedure, the Baum-Welch or Expectation Maximization (EM) method (Rabiner and Juang, 1986a; Baldi and Brunak, 1998a), which adapts the transition and output parameters by continually estimating these parameters until $P(O|\lambda)$ has been locally maximized. The EM algorithm is an iterative method to find the maximum likelihood estimate (MLE). It will let us train both the transition probabilities A and the emission probabilities B of the HMM. It works by computing an initial estimate for the probabilities, then using those estimates to compute a better estimate, and so on, iteratively improving the probabilities that it learns. This iterative algorithm alternates between performing an expectation step (E-step) and a maximization step (M-step). In an E-step, the expected number of times each transition is computed (the expected log-likelihood) and emission is used for the training set. In an M-step, the transition and emission parameters, that maximize the expected log-likelihood in the E-step are updated, using re-estimation formulas. The EM algorithm includes three steps of initialization, a series of iterations, and termination. In order to describe how to re-estimate HMM parameters, we first define the probability $\xi_t(i, j)$ of being in state S_i at time t and in state S_j at time $t+1$, as following:

$$\xi_t(i, j) = P(q_t = S_i, q_{t+1} = S_j | O, \lambda)$$

1. Iteration

Each cycle of EM iteration involves two steps, an E-step followed by an M-step, alternately optimizing the log-likelihood with respect to the posterior probabilities and parameters, respectively. In E-step we calculate the posterior probability of latent data using the current estimate for the parameters (π, α, β) of the model λ at time t . To perform the E-step, the expected log-likelihood function is maximized under the current estimated parameters and is computed, by using the estimated posterior probabilities of hidden data. In M-step: the new parameters that maximize the expected log-likelihood found in the E-step are estimated. From the definitions of forward and backward variables, we can calculate $\xi_t(i, j)$, which represents the posterior state probabilities of a variable and of the state combinations of two adjacent variables. We can write

$$\xi_t(i, j) = \frac{\alpha_t(i) a_{ij} b_j(O_{t+1}) \beta_{t+1}(j)}{P(O|\lambda)}$$

where the numerator term is $P(q_t = S_i, q_{t+1} = S_j | O, \lambda)$ and $P(O|\lambda) = \sum_{i=1}^N \sum_{j=1}^N \alpha_t(i) a_{ij} b_j(O_{t+1}) \beta_{t+1}(j)$ is the proper normalization factor for $\xi_t(i, j)$. We need to introduce another auxiliary variable, $\delta_t(i) = P(q_t = S_i | O, \lambda)$. It is the probability of being in the state S_i at time i , given the observation sequence and the model. In forward and backward variables this can be expressed by

$$\delta_t(i) = \frac{\alpha_t(i) \beta_{t+1}(i)}{\sum_{i=1}^N \alpha_t(i) \beta_t(i)}$$

Then, we can see that the relationship between $\delta_t(i)$ and $\xi_t(i, j)$ is given by

$$\delta_t(i) = \sum_{j=1}^N \xi_t(i, j), \quad 1 \leq i \leq N, \quad 1 \leq t \leq T$$

If we sum over $\delta_t(i)$ over the time index t , we obtain the expected number of transitions from state S_i , while, summing $\xi_t(i, j)$ over the time, we obtain the expected number of transitions from state S_i to state S_j . Then, we can use again the Baum-Welch method to re-estimate the HMM parameters as follows

$$\begin{aligned} \bar{\pi}_i &= \text{expected frequency in state } S_i \text{ at time } t = 1 \\ \bar{a}_{ij} &= \frac{\text{expected number of transitions from state } S_i \text{ to state } S_j}{\text{expected number of transitions from state } S_i} \\ \bar{b}_i(k) &= \frac{\text{expected number of times in state } j \text{ and observing symbol } v_k}{\text{expected number of times in state } j} \end{aligned}$$

2. Termination

If we apply this procedure iteratively, (Baum and Sell, 1968a; Baum et al., 1970a) using $\bar{\lambda}(\bar{\pi}, \bar{a}, \bar{b})$ in place of λ , and we repeat the calculation of the parameters, we can improve that the probability of O being observed from the model until convergence is reached. The final result of this re-estimation procedure is called maximum likelihood estimate of the HMM. The re-estimation parameters can be derived by maximizing the auxiliary function

$$Q(\lambda, \bar{\lambda}) = \sum_Q P(Q|O, \lambda) \log [P(O|Q, \bar{\lambda})]$$

over λ . The maximization of $Q(\lambda, \bar{\lambda})$ leads to increased likelihood

$$\max_{\bar{\lambda}} Q(\lambda, \bar{\lambda}) \Rightarrow P(O|\bar{\lambda}) \geq P(O|\lambda)$$

Case Study

We consider an application of HMMs to the finding problem of the CpG islands in a DNA sequence (Ron, Lecture Notes). For this purpose, we define CpG islands as regions of DNA with a high frequency of CpG sites, where a cytosine nucleotide is followed by a guanine nucleotide in the linear sequence of bases along its 5' → 3' direction. The CG pair of nucleotides is the most infrequent dinucleotide in many genomes. This is because cytosines C in CpG dinucleotides are vulnerable to a process, called methylation, that can change with a high chance in mutating to a T. The methylation process is suppressed in areas around genes and hence these areas contain a relatively high concentration of the CpG dinucleotide. Such regions are called CpG islands, whose length varies from few hundreds to few thousands bases, with a GC content of greater than 50% and a ratio of observed-to-expected CpG number above 60%. The presence of a CpG island is often associated with the start of the gene (promoter regions) in the most mammalian genome and thus the presence of a CpG island is an important signal for gene finding. Then, we consider an HMM for detecting CpG islands in a DNA sequence. In this case, the model contains eight states corresponding to the four symbols of the alphabet $\Sigma = \{A, C, G, T\}$, where the states and emitted symbols are shown in Fig. 7 and we consider two possible conditions: a DNA sequence is a CpG island (labeled +) or a DNA sequence is non-CpG island (labeled -). Considering a DNA sequence $X = (x_1, \dots, x_L)$, the question is to decide whether X is a CpG island.

Results

In the case study we ask if given a short sequence, is it from a CpG island or not. To answer this question, we can estimate the transition probabilities from statistical data about CpG islands and non-CpG islands and then we can build two Markov chains, one for each. Then given a sequence, we compute the probability p of obtaining the sequence in the CpG island Markov chain, and the probability q of obtaining the sequence in the non-CpG island Markov chain. The odds ratio or log-odds ratio of these two

T [−]	$\frac{1-q}{4}$	$\frac{1-q}{4}$	$\frac{1-q}{4}$	$\frac{1-q}{4}$	0.18 <i>q</i>	0.24 <i>q</i>	0.29 <i>q</i>	0.29 <i>q</i>

probabilities can be used to determine whether the sequence is coming from a CpG island or not. Then, for the CpG island Markov chain, we estimate a_{ij}^+ as follows

$$a_{ij}^+ = \frac{c_{ij}^+}{\sum_k c_{ik}^+}$$

where c_{ij}^+ is the number of times nucleotide j follows nucleotide i in the sequences labeled +. For the non-CpG island Markov chain, a_{ij}^- is estimated in a similar way. Now given a sequence X , we can compute $p(x)$ for each Markov chain; denoted these by $p(x|+)$ and $p(x|-)$, we can use the log-odds ratio $\log \frac{p(x|+)}{p(x|-)}$ to determine if X is coming from a CpG island or not; in fact, if $\log \frac{p(x|+)}{p(x|-)} > 0$, the sequence X is coming from a CpG island. Assuming that the transitions from the start state and to the end state are the same in both cases, the log-odds ratio can be expressed as following:

$$\log \frac{p(x|+)}{p(x|-)} = \log \frac{\prod_{i=0}^n a_{x_i x_{i+1}}^+}{\prod_{i=0}^n a_{x_i x_{i+1}}^-} = \sum_{i=1}^{n-1} \log \frac{a_{x_i x_{i+1}}^+}{a_{x_i x_{i+1}}^-}$$

We consider, as example, the short sequence CGCG; the transition probabilities for each of the two chains shown in **Table 3**. From the **Table 3**, we note that for the '+' Markov chain (CpG islands), the transition probabilities to C and G are higher. The log-odds ratio for this sequence is $\log \frac{0.27}{0.08} + \log \frac{0.34}{0.25} + \log \frac{0.27}{0.08} > 0$. Therefore, in this case, CGCG is coming from a CpG island. Instead, to verify if given a long sequence, does it contain a CpG island or not, we can incorporate both models (CpG islands and non-CpG islands) into one model. Then, we build a single Markov model consisting of both chains (+) and (−) described above as sub-chains, and with small transition probabilities between the two sub-chains. As before, we can estimate the transition probabilities between the two sub-chains by relying on known annotated sequences with all their transitions between CpG and non-CpG islands. is that there it not a one-to-one correspondence between the states and the symbols of the sequence. For instance, the symbol C can be generated by both states C^+ and C^- . For our purpose, we use an HMM (see **Fig. 7**): a sequence $X=(x_1, \dots, x_L)$ does not uniquely determine the path in the model and the states are hidden in the sense that the sequence itself does not reveal how it is generated. In this model, we define the probability for staying in a CpG island as p and the probability of staying outside as q , then the transition probabilities can be described in **Table 4**, derived from the transition probabilities given in **Table 3** under the assumption that we lose memory when moving from/into a CpG island, and that we ignore background probabilities. In this particular case, the emission probability of each state X^+ or X^- is exactly 1 for the symbol X and 0 for any other symbol.

Conclusions

HMM methods are used to solve a variety of biological problems, such as, for example, gene prediction, protein secondary structure prediction; in the last years, HMM-based profiles was applied to the protein-structure prediction and large-scale genome sequence analysis. In this paper we have presented an introduction to statistical approach of an HMM to show as these methods provide a conceptual framework for building complex models, just by drawing an intuitive picture. In particular, we have described the three problems of this theory with applications to the problem of finding specific patterns in biological sequences.

Linkage Disequilibrium

Barbara Calabrese, University “Magna Graecia” of Catanzaro, Catanzaro, Italy

Introduction

Throughout the human genome, a correlation structure exists across genetic variation of different loci. Such a correlation structure means that knowing the genotype at one locus might make available information about the genotype at a second locus. This correlation between variation at different loci is named linkage disequilibrium (LD) (Neale, 2010). Linkage disequilibrium refers to the non-random association of alleles at two or more loci in a general population. Linkage disequilibrium between two alleles is related to the time of the mutation events, genetic distance, and population history. Specifically, it can provide valuable information in locating disease variants from marker data.

In the following, linkage disequilibrium analysis is defined and the main methods and software tools for LD estimation are presented.

Linkage Disequilibrium

Consider two linked loci Locus 1 has alleles $A_1, A_2, \dots, A_m$ occurring at frequencies $p_1, p_2, \dots, p_m$ and Locus 2 has alleles $B_1, B_2, \dots, B_n$ occurring at frequencies $q_1, q_2, \dots, q_n$ in the population. The possible haplotypes can be denoted as $A_1B_1, A_1B_2, \dots, A_mB_n$ with frequencies $h_{11}, h_{12}, \dots, h_{mn}$. The two linked loci are said to be in linkage equilibrium (LE), if the occurrence of allele A_i and the occurrence of allele B_j in a haplotype are independent events. Conversely, alleles are in linkage disequilibrium (LD) when they do not occur randomly. Under linkage disequilibrium, haplotypes do not occur at the frequencies expected when the alleles were independent. Positive linkage disequilibrium exists when two alleles occur together on the same haplotype more often than expected, and negative LD exists when alleles occur together on the same haplotype less often than expected (Barnes, 2007).

Several linkage disequilibrium measures have been defined. The Linkage Disequilibrium Coefficient D is one measure of LD. For biallelic loci with alleles A and a at locus 1; B and b at locus 2, D is defined as (Eq. 1):

$$D_{AB} = P_{(AB)} - P_{(A)}P_{(B)} \quad (1)$$

LD is a property of two loci, not their alleles. Thus, the magnitude of the coefficient D is important and it does not depend on the choice of alleles. The range of values the linkage disequilibrium coefficient can take on varies with allele frequencies. The calculation of this parameter is quite simple, but it is very sensitive to allele frequencies at the extreme values of 0 to 1. Lewontin (1964) suggested D_0 , a normalized D calculated by dividing D by its theoretical maximum for the observed allele frequencies. D_0 can assume values from -1 to $+1$, but, generally, its absolute value is used.

Another measure of linkage disequilibrium is r^2 which is equivalent to the Pearson correlation coefficient (Pritchard and Przeworski, 2001). Define a random variable X_A to be 1 if the allele at the first locus is A and 0 if the allele is a. Define a random variable X_B to be 1 if the allele at the second locus is B and 0 if the allele is b. Then the correlation between these random variables is (Eq. 2):

$$r_{AB}^2 = \frac{D_{AB}^2}{p_A(1-p_A)p_B(1-p_B)} \quad (2)$$

Other methods for LD estimation include more sophisticated methods, such as the maximum likelihood methods (Gomez-Raya, 2012; Feder et al., 2012).

Tools for LD Estimation

Numerous software packages facilitate LD estimations (Henry et al., 2014). LDHub (Zheng et al., 2017) automates the linkage disequilibrium score regression analysis pipeline. LD Hub calculates the single nucleotide polymorphisms (SNP) heritability for the uploaded phenotype(s), and a genetic correlation matrix across traits. It can be considered as a useful hypothesis generating tool, providing an easy method of screening hundreds/thousands of traits for interesting genetic correlations that could subsequently be followed up in further detail by other approaches such as pathway analysis.

Overall LD (Zhao et al., 1999) offers a platform for estimating linkage disequilibrium (LD) between both markers and groups of markers. Overall LD is a standalone software with the aim of providing a permutation-based assessment based on a measure of the overall deviation from random association. It was tested with simulated data.

gwasMP (Wu et al., 2017) queries users' results with different thresholds of physical distance and/or Linkage Disequilibrium (LD). gwasMP is an online method that quantifies the physical distance, LD and difference in Minor Allele Frequency (MAF)

between the top associated single-nucleotide polymorphism (SNPs) identified from genome wide association studies (GWAS) and the underlying causal variants. The results are from simulations based on whole-genome sequencing data.

LDx (Feder *et al.*, 2012) is a computational tool for estimating linkage disequilibrium (LD) from pooled resequencing data.

Haploview comprehensive suite of tools for haplotype analysis for a wide variety of dataset sizes (Barrett, 2009; Barrett *et al.*, 2005). Haploview generates marker quality statistics, LD information, haplotype blocks, population haplotype frequencies and single marker association statistics in a user-friendly format. All the features are customizable and all computations performed in real time, even for datasets with hundreds of individuals and hundreds of markers.

Ldlink allows users to query pairwise linkage disequilibrium (LD) between single nucleotide polymorphisms (SNPs) (Machiela and Chanock, 2015; Machiela and Chanock, 2017). Ldlink is a web-based LD analysis tool providing access to several bioinformatics modules. The software integrates expanded population reference sets, updated functional annotations, and interactive output to explore possible functional variants in high LD. It can facilitate mapping of disease susceptibility regions and assist researchers in characterizing functional variants based on genotype-phenotype associations with potential clinical utility.

LDetect is a method to identify approximately independent blocks of linkage disequilibrium (LD) in the human genome (Berisa and Pickrell, 2016). These blocks enable automated analysis of multiple genome-wide association studies.

LDheatmap (Shin *et al.*, 2006) produces a graphical display, as a heat map, of measures of pairwise linkage disequilibria (LD) between single nucleotide polymorphisms (SNPs). From a data set that provides information on pairwise LD between SNPs in a genomic region, it plots color-coded values of the pairwise LD measurements and returns an object containing several components. The package also contains two functions which can be used to highlight or mark with a symbol pairwise LD measures on an LD heat map.

Ld.pairs (Schaid, 2004) calculates composite measures of linkage disequilibrium (LD). *ld.pairs* determines the variance, covariance and statistical tests for all pairs of alleles from two loci when linkage phase is not known. This application is based on the works of Weir and Cockerham on multiallelic loci. *ld.pairs* permits to allow more than two alleles at either of the loci, and so this general composite statistics is a competitor to the traditional likelihood-ratio statistic.

The main technical features of the cited tools have summarized in the following:

<i>Tool</i>	<i>Programming language</i>	<i>Interface</i>	<i>Operating System</i>
LDHub	Python	Command line	Unix/Linux
Overall LD	–	Command line	Unix/Linux
Haploview	Java	Graphical	Unix/Linux, MAC OS, Windows
Ldlink	–	Web	–
Ldetect	Python	Command line	Unix/Linux
LDHeatmap	R	Command line	Unix/Linux, MAC OS, Windows
Ld.pairs	R	Command line	Unix/Linux, MAC OS, Windows
gwasMP	–	Web	–
LDx	–	Command line	Unix Linux

Concluding Remarks

LD plays a fundamental role in gene mapping, both as a tool for fine mapping of complex disease genes and in proposed genomewide association studies. LD is also of interest for what it can reveal about evolution of populations. In this contribution, linkage disequilibrium has been formally defined. Different methods for linkage disequilibrium estimation have been introduced and discussed.

Introduction to the Non-Parametric Bootstrap

Daniel Berrar, Tokyo Institute of Technology, Tokyo, Japan

© 2019 Elsevier Inc. All rights reserved.

Introduction

The *bootstrap* is a computation-intensive data resampling methodology for assessing the accuracy of statistical estimates and for making statistical inferences about unknown population parameters (Efron, 1979, 1981, 1987; Efron and Tibshirani, 1986, 1993; Davison and Hinkley, 1997). A central question of inferential statistics is the following: How accurate is the sample statistic $\hat{\theta}$ as an estimator for an unknown population parameter θ ? The key to this question is the *sampling distribution* of $\hat{\theta}$. Suppose that we are interested in the population mean, μ . It is well known that the sample mean, $\bar{x}$, is the best point estimate for μ , and its sampling distribution can be analytically derived. However, for more intricate statistics (for example, performance measures of predictive models), it may be very difficult or even impossible to find the theoretical sampling distribution. Here, the bootstrap provides a solution.

In theory, to obtain the sampling distribution of our statistic of interest, we would need to draw all or infinitely many random samples from the population and compute the statistic for each sample. In practice, we (usually) have only one sample from the population. At the heart of the bootstrap is the idea that the available sample is a good estimate of the population of interest. So instead of drawing random samples from the population, we draw random samples from our estimate. These “samples from a sample” are called *bootstrap sets* or *bootstrap samples*. From each bootstrap sample, we then compute our statistic of interest. The spread and the shape of the distribution of these *bootstrap statistics* tell us something about the sampling distribution of the sample statistic, which provides useful information for making inferences about the population parameter. Now the etymological roots of the methodology also become clear: The name is derived from the phrase “to pull oneself up by one’s own bootstrap,” which implies that a thing is being built by using the thing itself – by drawing samples from the sample, we are building a bootstrap distribution.

There are essentially two different types of bootstraps. Without specific assumptions or a particular model for the population under investigation, the bootstrap is called *non-parametric*; otherwise, it is called *parametric* (Berrar and Dubitzky, 2013). Like random permutation methods and the jackknife, the bootstrap belongs to the family of Monte Carlo resampling methods (Baguley, 2012). Essentially, these methods differ with respect to how the sampling is done. Both the jackknife and random permutation methods perform sampling *without* replacement, whereas sampling is done *with* replacement in the bootstrap.

This article provides an introduction to the ordinary non-parametric bootstrap, which is arguably the most fundamental type. Here, we consider only the case that the population parameter and sample statistic are scalars. The focus is on the key ideas and two applications that are particularly relevant for bioinformatics: How to derive basic bootstrap confidence intervals, and how to assess the prediction error of a statistical model (for example, a classifier). For more theoretical details, see Efron and Tibshirani (1986, 1993), Dixon (2006). For an excellent discussion of the role of the bootstrap in statistics education, see Hesterberg (2015).

Notation

We begin with some basic terms, which largely follow the standard statistical notation (Davison and Hinkley, 1997). Greek lower case letters usually denote population parameters, for example, μ denotes the population mean. Roman upper case letters, such as X , usually denote sample statistics. For instance, $X = x_i$ means that the random variable X assumes a particular value x_i . The exception is N , which refers to the population size. $E(X)$ denotes the expected value or mean of X .

The probability distribution of X is called *sampling distribution* of X . The probability that a real-valued random variable X is smaller than, or equal to, a particular value x_0 is denoted by $P(X \leq x_0) = \mathcal{F}_X(x_0)$, which is called the *cumulative distribution function* (CDF) of X . The unknown parameter of interest is commonly denoted by θ , which could represent the mean or any other parameter. The symbol $\hat{\cdot}$ indicates an estimate. For example, the sample statistic $\hat{\theta}$ is an estimate for θ ; therefore, $\hat{\theta}$ is also called the *estimator* and θ is called the *estimand*. The standard deviation of the sampling distribution of the sample statistic $\hat{\theta}$ is called the *standard error* of $\hat{\theta}$. Finally, the symbol $*$ indicates a bootstrap statistic.

Note that a parameter has a fixed but (usually) unknown value and is therefore a constant. By contrast, a sample statistic is a random variable because it depends on the random makeup of the sample from which it was calculated. In the frequentist paradigm, sample statistics are random variables, and consequently, they have a sampling distribution; parameters, on the other hand, do not, since they are not random variables.

Sampling Distribution of a Sample Statistic

Let us assume that we have a data set D , which is a random sample from the population of interest. The data set has n elements, $x_1, x_2, \dots, x_n$. We will assume that the elements in our random sample are the real-valued outcomes of independent and identically distributed (iid) random variables $X_1, X_2, \dots, X_n$. The *probability density function* (PDF) of these random variables is denoted by f , and their cumulative distribution function is denoted by $\mathcal{F}$. Both f and $\mathcal{F}$ are characteristics of the population and therefore unknown,

just like the population parameter that we are interested in. We use the sample to make inferences about the unknown population parameter θ by calculating the statistic $\hat{\theta}$ from the sample data.

The population parameter can be thought of as a function of the population data, i.e., $\theta = t(x)$, where x denotes the population data and $t(\cdot)$ is a statistical function. This function tells us how to calculate θ from the data. For instance, let us assume that θ denotes the population mean, μ , and let us assume that the population elements are countably finite. Then $\mu = t(x) = \frac{1}{N} \sum_{i=1}^N x_i$, where N is the number of elements in the population. The same statistical function may be used to calculate the sample statistic, $\hat{\theta} = t(x)$, where x now denotes the sample data. For example, the sample mean is calculated as $\bar{x} = t(x) = \frac{1}{n} \sum_{i=1}^n x_i$, where n is the number of elements in the sample. In non-parametric analysis, the *empirical distribution function* (EDF), denoted by $\hat{\mathcal{F}}$, is an estimate of the cumulative distribution function, $\mathcal{F}$. Many simple statistics can be regarded as properties of the empirical distribution function (Davison and Hinkley, 1997). For example, let us consider the discrete case, where each x_i has the probability $\frac{1}{n}$ of being sampled. The sample mean, $\bar{x}$, is the same as the mean of the empirical distribution function, $\hat{\mathcal{F}}$,

$$\hat{\mathcal{F}}(x) = \frac{1}{n} \sum_{i=1}^n H(x - x_i), \quad \text{with} \quad (1)$$

$$H(u) = \begin{cases} 1, & \text{if } u \geq 0 \\ 0, & \text{otherwise} \end{cases}$$

where $H(\cdot)$ is the Heaviside function. Both the population parameter and the sample statistic can be expressed as a function of their underlying distribution functions: $\theta = t(\mathcal{F})$ and $\hat{\theta} = t(\hat{\mathcal{F}})$. The reason is that the parameter can be considered a characteristic of the population, which is described by its cumulative distribution function, $\mathcal{F}$. Similarly, the value of the sample statistic is a function of the empirical distribution of the sample elements, $\hat{\mathcal{F}}$. Not all estimators, however, are exactly of the form $\hat{\theta} = t(\hat{\mathcal{F}})$ (Davison and Hinkley, 1997); for example, the unbiased sample variance is $\frac{n}{n-1} t(\hat{\mathcal{F}})$. More precisely, therefore, it should be stated that $\hat{\theta} = t_n(\hat{\mathcal{F}})$ and $t_n \rightarrow t$ as $n \rightarrow \infty$. Here, we will ignore this detail, as it is irrelevant for the explanation of the non-parametric bootstrap.

The idea of random sampling from a population is illustrated in Fig. 1. As we have seen, the sample statistic, $\hat{\theta}$, can be thought of as a function of the empirical distribution, $\hat{\mathcal{F}}$, of the data in that particular sample. Clearly, if we drew another random sample, then most certainly we would obtain a slightly different value of $\hat{\theta}$. This idea is illustrated by $\hat{\theta}_2$ and $\hat{\theta}_k$ in Fig. 1. Assume that $t(\cdot)$ is the function for the arithmetic mean. It is plausible that sometimes, $\hat{\theta} = \bar{X}$ is a bit larger than $\theta = \mu$, sometimes a bit smaller, but on average, the sample mean and the population mean are the same. In fact, it can be proved that the expected value of the sample mean is the population mean, i.e., $E(\bar{X}) = \mu$.

Two characteristics of an estimator are its bias, β , and variance, $\sigma_{\hat{\theta}}^2$. The bias is the systematic error, i.e., the difference between the estimator's expected value, $E(\hat{\theta})$, and the true value of the estimand, θ , i.e., $\beta = E(\hat{\theta}) - \theta$. An estimator is said to be *unbiased* if its bias is zero. Hence, the sample mean $\bar{X}$ is an unbiased estimator of μ .

Consider a sample statistic $\hat{\theta}$ with mean $\mu_{\hat{\theta}} = \theta + \beta$ and standard deviation $\sigma_{\hat{\theta}}$, and assume that $\hat{\theta}$ is normally distributed, $\hat{\theta} \sim \mathcal{N}(\mu_{\hat{\theta}}, \sigma_{\hat{\theta}}^2)$. The probability that $\hat{\theta}$ takes on a value smaller than, or equal to, a particular value $\hat{\theta}_0$ is

$$P(\hat{\theta} \leq \hat{\theta}_0) = \Phi\left(\frac{\hat{\theta}_0 - \mu_{\hat{\theta}}}{\sigma_{\hat{\theta}}}\right) = \Phi\left(\frac{\hat{\theta}_0 - (\theta + \beta)}{\sigma_{\hat{\theta}}}\right) \quad (2)$$

where $\Phi(\cdot)$ denotes the standard normal cumulative distribution function. Furthermore,

$$P((\theta + \beta) - z_{1-\frac{\alpha}{2}} \cdot \sigma_{\hat{\theta}} \leq \hat{\theta} \leq (\theta + \beta) + z_{1-\frac{\alpha}{2}} \cdot \sigma_{\hat{\theta}}) = 1 - \alpha \quad (3)$$

where $z_{1-\frac{\alpha}{2}} = \Phi^{-1}(1 - \frac{\alpha}{2})$ is the quantile of the standard normal distribution for probability $1 - \frac{\alpha}{2}$. For example, if $\alpha = 0.05$, then $z_{0.975} = 1.96$. Rearranging Eq. (3) leads to the following identity $\hat{\theta}$ for the population parameter θ ,

$$P((\hat{\theta} - \beta) - z_{1-\frac{\alpha}{2}} \cdot \sigma_{\hat{\theta}} \leq \theta \leq (\hat{\theta} - \beta) + z_{1-\frac{\alpha}{2}} \cdot \sigma_{\hat{\theta}}) = 1 - \alpha \quad (4)$$

Fig. 1 Random sampling from a population with unknown parameter θ . The sample statistic $\hat{\theta}$ is the estimator for the parameter (i.e., the estimand). Both the statistic and the parameter depend on their underlying distribution functions $\hat{\mathcal{F}}$ and $\mathcal{F}$, respectively.

For example, let $\hat{\theta}$ be the sample mean, $\bar{X}$. It is well known that the sampling distribution of the sample mean is a normal distribution with mean $\mu\bar{X} = E(\bar{X}) = \mu$ and standard deviation $\sigma_{\bar{X}} = \frac{\sigma}{\sqrt{n}}$, if the population has a normal distribution (with standard deviation σ) or if the sample size is sufficiently large (usually, $n \geq 30$) (Fig. 2). The sample mean is an unbiased estimator of the population mean, as $\beta = E(\bar{X}) - \mu = \mu - \mu = 0$. A $(1-\alpha) \times 100\%$ confidence interval for the population mean μ is now given by

$$\bar{x} \pm z_{1-\frac{\alpha}{2}} \cdot \frac{\sigma}{\sqrt{n}} \quad (5)$$

In practice, the population standard deviation is usually not known, and the confidence interval is calculated based on Student's t -distribution. The Student- t confidence interval for the population mean is calculated as

$$\bar{x} \pm t_{v, 1-\frac{\alpha}{2}} \cdot \frac{s}{\sqrt{n}} \quad (6)$$

where $t_{v, 1-\frac{\alpha}{2}}$ is the quantile of the t -distribution with v degrees of freedom, with $v = n - 1$, and $s = \sqrt{\frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})^2}$ is the sample standard deviation.

So if we know the bias and variance of the sample statistic, then we can make inferences about the population parameter. For the sample mean, this is no problem, but what about more intricate statistics? Let us consider bias and variance as a function of the underlying distribution,

$$\beta = E(\hat{\theta}|\mathcal{F}) - t(\mathcal{F}) \quad (7)$$

$$\sigma\hat{\theta}^2 = \text{Var}(\hat{\theta}|\mathcal{F}) \quad (8)$$

Using $\hat{\mathcal{F}}$ as an estimate for $\mathcal{F}$, we obtain estimates of bias and variance,

$$\hat{\beta} = E(\hat{\theta}|\hat{\mathcal{F}}) - t(\hat{\mathcal{F}}) \quad (9)$$

$$\hat{\sigma}\hat{\theta}^2 = \text{Var}(\hat{\theta}|\hat{\mathcal{F}}) \quad (10)$$

which are called *bootstrap estimates* (Davison and Hinkley, 1997). This illustrates the *plug-in principle* (Hesterberg, 2015) of the bootstrap: When something is unknown, an estimate is plugged in instead.

Fig. 2 (a) Random sampling from a population with unknown mean μ . The estimator for the population mean is the sample mean, $\bar{X}$. The sample mean is a random variable and takes on the values $\bar{x}_i$, which depend on the concrete makeup of the random sample. (b) Sampling distribution of the sample mean, $\bar{X}$. The distribution is normal, $\bar{X} \sim \mathcal{N}\left(\mu, \frac{\sigma^2}{n}\right)$, i.e., the distribution is centered at the population mean, μ . The value $z_{1-\frac{\alpha}{2}}$ is the quantile of the standard normal distribution for probability $1 - \frac{\alpha}{2}$. For example, $z_{0.975} = 1.96$ for $\alpha = 0.05$.

Fig. 3 Ordinary non-parametric bootstrap. The available data set (i.e., original sample) is repeatedly sampled (with replacement) to generate b bootstrap sets B_i , $i = 1..b$. Each bootstrap set has the same number of elements, n , as the original data set D . Because of the sampling with replacement, some elements can occur more than once in one bootstrap set, while others do not occur at all.

Ordinary Non-Parametric Bootstrap

The *ordinary non-parametric bootstrap* procedure can be described as follows:

1. The available data set D is assumed to be a representative sample from the population of interest. This data set contains a total of n elements, $x_1, x_2, \dots, x_n$.
2. From D , calculate the statistic $\hat{\theta}$, which is the estimate for the population parameter, θ .
3. Generate a bootstrap set, B , by randomly sampling n instances with replacement from D . The sampling is uniform, which means that each of the n elements in D has the same probability, $\frac{1}{n}$, of being selected. (More intricate sampling approaches, such as sampling with noise, are beyond the scope of this article.)
4. Repeat step (3) b times to generate b bootstrap sets, $B_1, B_2, \dots, B_b$ (Fig. 3).
5. Calculate the statistic $\hat{\theta}_i^*$ from the i th bootstrap set B_i .
6. Repeat step (5) for all b bootstrap sets.

From a data set with n elements, we could theoretically generate $\binom{2n-1}{n}$ distinct bootstrap sets. If n is not too large, we could perform an *exhaustive bootstrap* by constructing all possible sets instead of random sampling. This approach is also referred to as the *theoretical bootstrap* (Hesterberg, 2015). In practice, however, n is usually too large, and we generate several hundreds or thousands of bootstrap samples. This approach is an example of *Monte Carlo sampling*. Hesterberg suggests $b=1000$ for a rough approximation and $b \geq 10000$ for more accuracy (Hesterberg, 2015).

After the described procedure, we obtain the *empirical* or *bootstrap distribution* of all $\hat{\theta}_i^*$, from which we can infer the *bootstrap cumulative distribution function*, $\hat{\mathcal{F}}^*$. The mean, bias, and variance of $\hat{\theta}^*$ are:

$$\bar{\hat{\theta}}^* = \frac{1}{b} \sum_{i=1}^b \hat{\theta}_i^* \quad (11)$$

$$\text{bias}\{\hat{\theta}^*\} = E(\hat{\theta}_i^*) - \hat{\theta} = \bar{\hat{\theta}}^* - \hat{\theta} \quad (12)$$

$$\hat{\sigma}_{\hat{\theta}^*}^2 = \frac{1}{b-1} \sum_{i=1}^b (\hat{\theta}_i^* - \bar{\hat{\theta}}^*)^2 \quad (13)$$

It is important to note that the bootstrap distribution is centered at the observed statistic, $\hat{\theta}$, not at the population parameter, θ . Our best estimate for the population parameter (say, the mean μ) is therefore still our original sample statistic (i.e., $\bar{x}$ for μ), not the average of all bootstrap estimates, $\bar{\hat{\theta}}^*$. As the bootstrap distribution is not centered at the population parameter, the quantiles of the bootstrap distribution are usually different from the quantiles of the theoretical sampling distribution of the sample statistic, $\hat{\theta}$. This means that the bootstrap quantiles are not meaningful estimates for the quantiles of $\hat{\theta}$. However, the bootstrap quantiles are useful to estimate the quantiles and CDF of $\hat{\theta} - \theta$ and to estimate the standard deviation of $\hat{\theta}$. This idea is illustrated in Fig. 4 using the sample mean $\bar{X}$ as an example. Note that in Fig. 4(d), the standard deviation of the bootstrap statistic is only slightly larger than the standard deviation of the theoretical sampling distribution of the sample statistic. The example in Fig. 4 is just an illustration of the principle of bootstrapping. For the sample mean, the bootstrap is actually not needed because we already know the theoretical sampling distribution of $\hat{\theta}$. For many other statistics, however, that is not the case.

Basic Bootstrap Confidence Intervals

We now describe two basic bootstrap confidence intervals: The *bootstrap percentile interval* and the *bootstrap-t interval* (Efron and Tibshirani, 1993). More advanced intervals are described in Efron (1987), DiCiccio and Efron (1996).

Bootstrap Percentile Confidence Interval

The bootstrap percentile confidence interval is arguably the simplest and most intuitive bootstrap interval. It is derived as follows.

1. Generate b bootstrap sets by repeatedly sampling with replacement from the available data set (i.e., original sample) D . For each bootstrap sample B_i , calculate the sample statistic $\hat{\theta}_i^*$.
2. Find the $\frac{\alpha}{2}$ and $1 - \frac{\alpha}{2}$ percentiles of the distribution of $\hat{\theta}_i^*$. These percentiles are denoted by $\hat{\theta}_{\frac{\alpha}{2}}^*$ and $\hat{\theta}_{1-\frac{\alpha}{2}}^*$, respectively. (In R, the function `quantile(Y, c(0.025, 0.975))` gives the 2.5% and 97.5% percentile for the data in Y .)
3. A $(1-\alpha) \times 100\%$ bootstrap percentile confidence interval for θ is given by

$$\left[\hat{\theta}_{\frac{\alpha}{2}}^*, \hat{\theta}_{1-\frac{\alpha}{2}}^* \right] \quad (14)$$

Fig. 4 (a) An example of a population of interest, representing $N=1000$ instances x_i from a normal mixture of two distributions, $\mathcal{N}_1(0, 4)$ and $\mathcal{N}_2(6, 1)$. The population mean and standard deviation are $\mu=3$ and $\sigma=3.37$, respectively. (b) The sampling distribution of the sample mean is normal, with mean $\mu_{\bar{X}} = \mu$ and standard deviation $\sigma_{\bar{X}} = \frac{\sigma}{\sqrt{n}} = 0.57$. (c) A random sample of $n=35$ instances from the population. The sample mean is $\bar{x}=2.5$ and the standard deviation is $s=3.72$. (d) Bootstrap (empirical) distribution of the bootstrap estimate $\bar{X}^*$ based on $b=10000$ bootstrap sets sampled from the data in (c). The bootstrap distribution has mean $\mu_{\bar{X}^*} = \bar{x}=2.5$ and standard deviation $\sigma_{\bar{X}^*} = 0.62$.

Bootstrap- t Confidence Interval

The bootstrap- t interval is constructed as follows.

1. Draw b bootstrap samples by repeatedly sampling with replacement from the available data set D . For each bootstrap sample B_i , calculate

$$Z_i^* = \frac{\hat{\theta}_i^* - \hat{\theta}}{\widehat{\text{SE}}_i^*} \quad (15)$$

where $\widehat{\text{SE}}_i^*$ is the estimate of the standard error of $\hat{\theta}^*$ based on the data in B_i . This estimate is calculated as the standard deviation of all values in B_i divided by the square root of the sample size, $\widehat{\text{SE}}_i^* = \frac{\hat{\sigma}_i^*}{\sqrt{n}}$. The random variable Z_i^* is called an *approximate pivot* (Efron and Tibshirani, 1993).

2. Find the $\frac{\alpha}{2}$ and $1 - \frac{\alpha}{2}$ percentiles of the distribution of Z_i^* . Denote these percentiles by $\hat{t}_{\frac{\alpha}{2}}^*$ and $\hat{t}_{1-\frac{\alpha}{2}}^*$, respectively.
3. A $(1-\alpha) \times 100\%$ bootstrap- t interval for the parameter θ is given by

$$\left[\hat{\theta} - \hat{t}_{1-\frac{\alpha}{2}}^* \cdot \frac{s}{\sqrt{n}}, \hat{\theta} - \hat{t}_{\frac{\alpha}{2}}^* \cdot \frac{s}{\sqrt{n}} \right] \quad (16)$$

where s denotes again the standard deviation of the sample (i.e., the original data set D).

Table 1 95% confidence intervals for the population mean based on the random sample in Fig. 4(a)

Method	95% confidence interval	Width
Bootstrap percentile interval	[1.238, 3.696]	2.458
Bootstrap- <i>t</i> interval	[1.184, 3.769]	2.585
Student- <i>t</i> interval	[1.224, 3.780]	2.556
Normal- <i>z</i> interval	[1.387, 3.617]	2.230

Eq. (16) is similar to the common Student-*t* interval, except that the *t*-value is substituted by the bootstrap estimates $\hat{t}_{1-\frac{\alpha}{2}}^*$ and $\hat{t}_{\frac{\alpha}{2}}^*$. These estimates are not necessarily symmetric about 0, in contrast to the percentiles of the standard normal and *t*-distribution. Whereas the common *z*- and *t*-intervals are always symmetric about θ , bootstrap-*t* intervals (and bootstrap percentile intervals) are not necessarily symmetric.

It may be surprising that Eq. (16) does not include a term for the bias (cf. Eq. (4)). Indeed, we could calculate a bias-corrected estimate as $\hat{\theta} - \text{bias}\{\hat{\theta}^*\} = \hat{\theta} - (\hat{\theta}^* - \hat{\theta}) = 2\hat{\theta} - \hat{\theta}^*$. However, bias estimates can have a high variability (Efron and Tibshirani, 1993; Hesterberg, 2015), so it is not advisable to perform this correction.

Table 1 shows the two bootstrap 95% confidence intervals for the population mean μ of the example population (Fig. 4(a)). For comparison, the common *z*- and *t*-intervals are also shown.

For the example data in Fig. 4, $n=35$ seems to be sufficient for a reliable bootstrap confidence interval. The width of both bootstrap intervals is comparable to that of the Student-*t* interval. The *z*-interval is of course the most accurate interval in this example because it uses the population standard deviation, σ . For real-world data sets, however, it is usually not possible to derive a *z*-interval, as σ is almost never known.

Both the bootstrap-*t* interval and the bootstrap percentile interval are only first-order accurate, which means that the actual one-sided coverage probabilities differ from the nominal values by $\mathcal{O}\left(\frac{1}{\sqrt{n}}\right)$. Hence, both intervals tend to be too narrow for small n (Hesterberg, 2015). For small sample sizes, the bootstrap intervals offer therefore no improvement over the Student-*t* interval. On the other hand, when n is large, bootstrap intervals usually perform better, particularly for skewed distributions (Hesterberg, 2015). The reason is that common confidence intervals based on the standard normal and *t*-distribution are symmetric about zero, whereas bootstrap percentile intervals and bootstrap-*t* intervals may be asymmetric, which can improve coverage (Efron and Tibshirani, 1993). In fact, the Student-*t* interval was shown to be surprisingly inaccurate when the population distribution is skewed, even if the sample size is much larger than 30 (Hesterberg, 2011). For large samples from skewed populations, bootstrap-*t* intervals tend to have a better coverage than the Student-*t* intervals and are therefore preferable. The bootstrap-*t* interval is particularly suitable to location statistics such as the mean or median (Efron and Tibshirani, 1993).

When the bootstrap distribution is approximately normal and the bias is small, the bootstrap-*t* interval and the percentile bootstrap interval will agree closely. If that is not the case, Hesterberg et al. (2010) caution against the use of either interval.

Bootstrap Estimates of Prediction Error

When only one data set is available to develop and test a statistical model (for example, a classifier or regression model), the bootstrap is an effective technique to estimate the true prediction error (Berrar and Dubitzky, 2013). This true prediction error represents the unknown population parameter. Let us assume that a data set D contains n instances (or cases) x_i , $i=1..n$, and each instance is described by a set of features. Let us further assume that with each instance, exactly one target label y_i is associated. In the case of classification, y_i is a discrete class label, $y_i \in \{y_1, y_2, \dots, y_k\}$, where k indicates the number of distinct classes. In the case of regression, the target is a real value, $y_i \in \mathbb{R}$. A statistical model $f(\cdot)$ estimates the target y_i of the case x_i as $f(x_i) = \hat{y}_i$. The estimation error is quantified by a *loss function*, $\mathcal{L}(y_i, \hat{y}_i)$. For example, in the case of classification and the 0–1 loss function, the loss is 1 if $y_i \neq \hat{y}_i$ and 0 otherwise. In the case of a regression problem, the loss function generally involves a form of squared error. The *bootstrap estimate of the prediction error* is calculated as follows.

1. Generate b bootstrap sets B_j , $j=1..b$, by repeatedly sampling (with replacement) n cases from D .
2. Use the bootstrap set B_j as training set to build the model f_j^* .
3. Calculate $f_j^*(x_i) = \hat{y}_i$, and then compute the loss function $\mathcal{L}(y_i, f_j^*(x_i))$.
4. The *bootstrap estimate of the prediction error*, $\hat{\varepsilon}^*$, is the average over all cases and all bootstrap sets,

$$\hat{\varepsilon}^* = \frac{1}{n} \sum_{i=1}^n \frac{1}{b} \sum_{j=1}^b \mathcal{L}(y_i, f_j^*(x_i)) \quad (17)$$

As the training sets B_j partially overlap with D , the error estimate $\hat{\varepsilon}^*$ is biased downward, which means that it is smaller than the true prediction error. A simple approach to alleviate the optimistic bias is to exclude those cases from the evaluation that served

already as training cases. Let S_{-i} denote the set of indices of the bootstrap samples that do not contain the case x_i , and let $|S_{-i}|$ denote the number of these indices. The *leave-one-out bootstrap estimate*, $\hat{e}_{loob}^*$, is defined as follows (Hastie et al., 2008).

$$\hat{e}_{loob}^* = \frac{1}{n} \sum_{i=1}^n \frac{1}{|S_{-i}|} \sum_{j \in S_{-i}} \mathcal{L}(y_i, \hat{f}_j^*(x_i)) \quad (18)$$

It is possible that all bootstrap samples contain the case x_i , and consequently that $|S_{-i}|=0$. To avoid a division by zero, the number of bootstrap samples, b , has to be sufficiently large to ensure that at least one of them does not contain x_i , or those cases that appear in all bootstrap samples should be omitted from Eq. (18).

The leave-one-out bootstrap estimate tends to overestimate the true prediction error; in other words, it has an upward bias. The reason is that the model is trained on only a subset of the available data because each bootstrap sample contains, on average, only about 63% of the data: The probability that a case x_i is selected for a bootstrap set in one random sampling is $\frac{1}{n}$, and the probability of not being selected is therefore $1 - \frac{1}{n}$. When the sampling is done n times, the probability that the case is not selected at all is $(1 - \frac{1}{n})^n$. Consequently, the probability that it is selected is $1 - (1 - \frac{1}{n})^n$. Note that $(1 - \frac{1}{n})^n \rightarrow e^{-1}$ for $n \rightarrow \infty$. Therefore, for sufficiently large n , the probability that a case x_i appears in a bootstrap set is approximately $1 - e^{-1} = 0.632$. This means that each bootstrap set has, on average, about 63% of distinct cases only – so about 37% of the available data are not used for training, which results in an overestimation of the prediction error. This overestimation can be corrected by considering the resubstitution error. The *bootstrap resubstitution error* is defined as follows (Hastie et al., 2008).

$$\hat{e}_{resub}^* = \frac{1}{n} \sum_{i=1}^n \frac{1}{|S_{+i}|} \sum_{j \in S_{+i}} \mathcal{L}(y_i, \hat{f}_j^*(x_i)) \quad (19)$$

where S_{+i} is the set of bootstrap set indices that contain the case x_i . The resubstitution error is also referred to as the *training error*. It has a downward bias, which means that it underestimates the true prediction error.

The *0.632 bootstrap error*, $\hat{e}_{0.632}^*$, is a weighted average of the overly optimistic resubstitution error and the overly pessimistic leave-one-out bootstrap error,

$$\hat{e}_{0.632}^* = 0.368 \cdot \hat{e}_{resub}^* + 0.632 \cdot \hat{e}_{loob}^* \quad (20)$$

The error estimate $\hat{e}_{0.632}^*$ still has a downward bias (Breiman et al., 1984), which the *.632 + bootstrap* corrects by adjusting the weights for the resubstitution error and leave-one-out bootstrap error,

$$\hat{e}_{0.632+}^* = (1 - w) \cdot \hat{e}_{resub}^* + w \cdot \hat{e}_{loob}^*, \quad \text{with} \quad (21)$$

$$w = \frac{0.632}{1 - 0.368\hat{R}} \quad (22)$$

$$\hat{R} = \frac{\hat{e}_{loob}^* - \hat{e}_{resub}^*}{\hat{e}_{random} - \hat{e}_{resub}^*} \quad (23)$$

The quantity $\hat{e}_{random}$ in Eq. (23) is an estimate of the no-information error rate, i.e., the expected error when the cases are statistically independent of their class labels. $\hat{R}$ is a measure of the relative overfitting rate, which ranges from 0 if $\hat{e}_{loob}^* = \hat{e}_{resub}^*$ (i.e., there is no overfitting) to 1 if $\hat{e}_{loob}^* = \hat{e}_{random}$. The weight w ranges from 0.632 (if $\hat{R} = 0$) to 1 (if $\hat{R} = 1$), and consequently, $\hat{e}_{0.632+}^*$ ranges from $\hat{e}_{0.632}^*$ to $\hat{e}_{loob}^*$. Hence, the weights in the *0.632 + bootstrap* error are not fixed, but they depend on the estimated degree of overfitting.

Discussion

The bootstrap is an extremely versatile methodology for statistical inference. It can be applied to problems that are intractable for standard approaches. For example, consider the problem of assessing the discriminatory power of a classification model based on genomic profiling. Typically, only a relatively small data set is available for both training and testing the model. The observed classification performance may be measured by balanced accuracy, area under the ROC curve, or any other metric that is deemed suitable for the problem at hand. But the observed performance value is only an estimate of the true discriminatory power for new, unseen cases from the same population. How accurate is this estimate? The bootstrap enables us to address this question.

The bootstrap is not the only data resampling methodology for this purpose, though. Molinaro et al. (2005) compared different resampling techniques for estimating the prediction error in the context of the small- n -large- p problem, i.e., in problems where the number of cases (n) is much smaller than the number of features (p). Such problems are not at all uncommon in the life sciences, for example, in classification studies involving gene expression data. The bias of the *0.632 + bootstrap* was found to be comparable to that of leave-one-out cross-validation and 10-fold cross-validation (Molinaro et al., 2005; Simon, 2007). According to Isaksson et al. (2008), however, both cross-validation and bootstrapping are unreliable for estimating the true prediction error when the data set is small, and they recommend Bayesian intervals based on a holdout test set.

The bootstrap spares us theoretical analysis, but at the expense of considerable computational costs due to the required repeated sampling. On the other hand, computational costs become increasingly negligible with the availability of relatively cheap computing power. Most statistical software tools nowadays include functions for bootstrapping; for example, the widely used

language and environment R (R Core Team, 2017) provides the package `boot` (Canty and Ripley, 2017) for parametric and non-parametric bootstrapping. In particular, a variety of bootstrap confidence intervals can be calculated with the function `boot.ci`. The R package `resample` provides various resampling functions for bootstrapping, jackknifing, and random permutation testing (Hesterberg, 2015).

The bootstrap can also serve as a useful teaching tool in introductory statistics courses (Hesterberg, 2015). Concepts such as repeated random sampling, standard errors, etc. might be explained in a more accessible way if the instructor complements statistical theory and formulas with histograms of sampling distributions.

Closing Remarks

The bootstrap is a powerful methodology that allows statistical inferences for a wide range of problems that are extremely difficult or even impossible to tackle by other means. The bootstrap therefore plays an important role in the sciences, both in research and education. At the heart of the bootstrap is the idea that the available data set is an estimate of the population of interest, and that we can repeatedly take random samples from that estimate. But if the available data set is too small, it is unlikely to be a good estimate. Researchers need to keep in mind that no amount of resampling will ever be a panacea for the lack of data. Also, error estimates based on resampling are no substitute for independent validation studies using new data.

Introduction

Proteins are among the most studied macromolecules in Biology and are central to the functioning of living organisms. They play a major role in many critical mechanisms such as signaling, transport, enzymatic reactions, and immune defense. The dysfunction or the over-expression of a protein can be responsible for various lethal diseases, such as cancer. The function of a protein is determined by its structure, which is determined by its sequence (Anfinsen, 1973). Understanding the relationship between the sequence and structure of proteins would help to unveil the mechanisms which underlie the functioning of living organisms, and allow designing drugs in order to regulate the expression of proteins in case of abnormal activity. In addition, the abilities of proteins to self-assemble and to serve as chemical reaction catalysts make proteins a first choice target for applications in bio-nanotechnologies (Voet *et al.*, 2014; Bale *et al.*, 2016) or enzyme design (Siegel *et al.*, 2010; Khersonsky *et al.*, 2011).

Protein structure prediction aims at determining the three-dimensional structure of a protein starting from its sequence. The methods for addressing this problem can be classified into two categories: homology modeling (template-based modeling) and *de novo* modeling. Homology modeling methods aim at identifying known protein structures with a similar sequence, relying on the observation that similar sequences generally fold into similar structures. The known structure is then used as a template to model the target protein. *De novo* modeling methods predict protein structures solely based on their amino acid sequences. While the main bottleneck for homology methods is the identification of a suitable template, the main difficulty for *de novo* methods is dealing with the astronomical size of the conformational search space.

As pointed out by Cyrus Levinthal in 1968, the number of degrees of freedom of proteins renders infeasible the exhaustive enumeration of all states (Levinthal, 1968). When dealing with *de novo* protein structure prediction, it is therefore crucial to devise strategies that allow exploring a meaningful portion of plausible states, such as the fragment-based approach, which has encountered great success in the last two decades as epitomized by the Rosetta macromolecular modeling software (Rohl *et al.*, 2004; Bradley *et al.*, 2005b; Leaver-Fay *et al.*, 2011). In this approach, small structural fragments, taken from proteins with known structures, are assembled together in order to construct a complete protein model. Using small structural fragments which are matched with the target protein sequence helps to reduce the search space size by discretization. However, with a reasonable setting using 25 fragments of 9 residues per overlapping sliding window, the size of the search space for a 100 residue long protein sequence is of the order of 10^{128} . With such a search space size, advanced sampling algorithms are needed. The discretization of the search space provided by the fragment-based approach facilitates the use of combinatorial optimization sampling methods, such as simulated annealing, and population-based techniques. Simulated annealing (Kirkpatrick *et al.*, 1983) is the default sampling algorithm in Rosetta. It is commonly used in hard optimization problems with rugged energy landscapes due to its well-known ability to escape local minima. *De novo* protein structure prediction typically requires the production of tens of thousands of models in order to be reliable. Parallel and distributed computer architectures are employed in order to perform the calculations in an acceptable time. Simulated annealing, being a single solution method, cannot share information between parallel search trajectories. Information sharing is one of the strength of population-based sampling methods such as Evolutionary Algorithms, which use it to enhance the exploration of the search space and to lower the risks of convergence toward local minima.

Evolutionary algorithms, and population-based meta-heuristics in general, are known to provide near-optimal solutions to many NP-hard optimization problems, such as *de novo* protein structure prediction. The scoring functions associated with protein structure prediction typically describe a rugged funnel-like landscape with many local minima. Combined with the huge size of the search space, this makes the protein structure prediction problem a suitable target for population-based meta-heuristics. Furthermore, NP-hardness proofs exist even for simplified protein structure prediction problem representations (Hart and Istrail, 1997). A variety of population-based sampling methods have been reported in the literature. Genetic algorithms (GA) certainly are the most well-known, and their application to protein structure prediction have been extensively studied in the last three decades. Simple lattice models, such as the well-known HP model proposed by Dill (1985), have been used to confirm the potential of GA for protein structure prediction and to design efficient variants (Unger and Moulton, 1993; Hoque *et al.*, 2005; Lin and Hsieh, 2009; Zhang *et al.*, 2010). However, even though these models are helpful in understanding the main driving forces behind protein folding and for devising new algorithms, they cannot be used to predict the 3D structure of real-world proteins. To this end, many studies have proposed GA variants working on more realistic representations of proteins, beginning in the mid-nineties (Dandekar and Argos, 1992, 1994, 1996; Sun, 1993; Pedersen and Moulton, 1995;) and continuing to the present (Sakae *et al.*, 2011; Saleh *et al.*, 2013; Olson and Shehu, 2013; Clausen and Shehu, 2014; Kandathil *et al.*, 2016; Garza-Fabre *et al.*, 2016). Besides GA, many other meta-heuristics have been

proposed such as Hidden Markov Models (HMM) (Park, 2005; Hamelryck *et al.*, 2006; Zhao *et al.*, 2008; Shmygelska and Levitt, 2009; Zhao *et al.*, 2010) or Estimation of Distribution Algorithms (Simoncini *et al.*, 2012, 2017; Simoncini and Zhang, 2013).

Evolutionary Algorithms

Evolutionary algorithms (EA) are general population-based optimization methods. Their search space sampling mechanisms and dynamics are inspired by the Theory of Evolution (Darwin, 1859). The metaphor employed in EA is summarized in Table 1. Similar to individuals evolving inside a species according to their fitness in the environment, solutions in a EA evolve in the search space in order to optimize an objective function and answer a problem.

Any EA follows the general scheme depicted in Algorithm 1. First, the population μ is initialized (line 1) and the solutions are evaluated (line 2). Then a cycle starts during which, at each iteration, a subpopulation λ is selected (line 4). The subpopulation λ is used to generate new solutions with stochastic variation operators (line 5). Each solution in the subpopulation λ is evaluated (line 6). Finally, the population μ is partially or totally replaced by the newly generated population. The iterative cycle continues until a stop criterion is met (line 3).

Algorithm 1 Evolutionary algorithm

6:    $\text{EvaluateFitness}(\lambda)$ 
7:    $\mu \leftarrow \text{ReplacePopulation}(\mu, \lambda)$ 
8: end while

```

In this section, we give an overview of evolutionary algorithms and discuss the key parameters that influence the search trajectories. We will focus on three subclasses of evolutionary algorithms: genetic algorithms, estimation of distribution algorithms, and memetic algorithms. We conclude this section with one of the main issues one must address when using evolutionary algorithms: the balance between exploration and exploitation.

Key Elements of Evolutionary Algorithms

The key elements of an EA are the problem representation, the choice of stochastic variation operators, and the population selection and replacement strategy.

Problem representation. Coming back to the evolutionary metaphor, the link between phenotype and genotype transposes to the link between problem statement and problem encoding. The two main elements of the problem encoding are the representation of solutions and the design of the objective function. The choice of these elements have a critical impact on the size of the search space and the shape of the *fitness landscape*, which can be seen as a map of the search space, with hills and valleys representing local minima attraction basins. Solutions can be encoded in many different ways, the most common being vectors of bits or integers. The objective function is derived from the problem statement. It can be exact, as for the well-known Traveling Salesman Problem, or approximate and empirically defined, as for the protein structure prediction problem.

Stochastic variation operators. Inspired by the theory of evolution, stochastic variation operators can be divided into two classes: crossover operators and mutation operators. Crossover operators are functions that take two solutions as input, whereas mutation operators are functions that take a single solution as input. The idea behind crossover operators is to randomly combine two good solutions with the hope of capturing good features from each of them, thereby generating a better solution. Many different crossover operators exist, the most popular being the one point crossover illustrated in Fig. 1. The one point crossover operator assumes that the solutions are vectors. Its principle is to randomly select a cutting point in

Fig. 1 Illustration of a one point crossover. A cutting point is arbitrarily chosen in the blue and green solutions. The part after the cutting point is swapped in order to create two new solutions.

order to delimit which part of the two solutions will be exchanged. Mutation operators typically randomly select a position in the solution and change its value. It can be seen as a neighborhood exploring move, whereas the crossover operation can be seen as a big jump in the fitness landscape.

Selection and replacement strategy. The way solutions are selected for recombination, and the way the new generation of solutions replaces the old, impacts the search dynamics and the convergence of EA. The two main approaches are the steady-state and generational schemes. In steady-state EA, two solutions are selected for recombination/mutation and the resulting solution is directly inserted in the population if it satisfies the prerequisite conditions. In generational EA, some solutions are selected in order to form a transition population from which a pool of new solutions will be generated by recombination and mutation. The new pool of solutions replaces the population totally or partially, once again according to some conditions. The conditions for replacement are user-defined, the most common being an elitist scheme where a fraction of the best solutions are preserved.

Genetic Algorithms

Genetic Algorithms (GA) were introduced by John Holland in 1975 (Holland, 1975). As with any evolutionary algorithm, GA rely on a metaphor of the Theory of Evolution (see Table 1). As suggested by Charles Darwin, a species evolves and adapts to its environment by means of variation and natural selection (Darwin, 1859). Good solutions to a problem can be seen as individuals well adapted to their environment. The basic idea of GA thus consists in combining solutions (genetic crossover), using local moves (mutations) and renewing the population with the best solutions (natural selection). Algorithm 2 describes a typical GA process. This algorithm is derived from the general EA scheme presented in Algorithm 1 by specifying the stochastic variation operators as crossover and mutation operations.

Algorithm 2 Genetic algorithm

```

2:  $\text{EvaluateFitness}(\mu)$ 
3: while  $\text{Continue}()$  do
4:    $\lambda \leftarrow \text{Selection}(\mu)$ 
5:    $\lambda \leftarrow \text{Crossover}(\lambda)$ 
6:    $\lambda \leftarrow \text{Mutation}(\lambda)$ 
7:    $\text{EvaluateFitness}(\lambda)$ 
8:    $\mu \leftarrow \text{ReplacePopulation}(\mu, \lambda)$ 
9: end while

```

Estimation of Distribution Algorithms

Estimation of distribution algorithms (EDA) were proposed by Muhlenbein and Paaß in 1996 (Muhlenbein and Paaß, 1996). Unlike GA and other EA, EDA does not use any crossover or mutation operators. Still, EDA shares enough similarities with EA to be considered to belong to this class. The general behavior of EDA is given in Algorithm 3. This algorithm follows the general EA scheme of Algorithm 1. The unique feature of EDA concerns the choice of the stochastic variation operators which do not explicitly apply recombination or mutation to generate solutions. A pool of good solutions is selected (line 4) and used to estimate their probability distribution (line 5). The population is then renewed by drawing solutions according to this distribution (line 6). Another difference with other EA is that the steady-state replacement scheme does not make sense in an EDA: the pool of solutions must contain enough solutions to permit the estimation of the probability distribution.

Algorithm 3 Estimation of distribution algorithm

```

1:  $\mu \leftarrow \text{InitializePopulation}()$ 
2:  $\text{EvaluateFitness}(\mu)$ 
3: while  $\text{Continue}()$  do
4:    $\lambda \leftarrow \text{Selection}(\mu)$ 
5:    $\delta \leftarrow \text{EstimationOfDistribution}(\lambda)$

```

Memetic Algorithms

Memetic algorithms, also known as Lamarckian EAs, were proposed by Moscato in 1989 (Moscato, 1989). A memetic algorithm follows the generic EA scheme described in Algorithm 4, and adds a local search step after the application of stochastic variation operators (line 6). The local search method can be any single solution neighborhood exploring algorithm, e.g., simulated annealing (Kirkpatrick *et al.*, 1983), Tabu search (Glover and Laguna, 1999), Iterated local search (Lourenco *et al.*, 2001). Memetic algorithms are often called hybrid genetic algorithms because of the hybridization between classic GA stochastic variation operators (crossover, mutation) and heuristics, i.e., domain specific local search methods. This kind of algorithm is very successful because of its natural tendency to efficiently balance search space exploration with stochastic variation and local intensification with heuristics.

Algorithm 4 Memetic algorithm

9: end while

```

Exploration Versus Exploitation

The balance between exploration and exploitation, or diversification and intensification, is a longstanding and well documented issue in population-based sampling (Črepinšek *et al.*, 2013). Exploration refers to search space sampling, and exploitation refers to local optimization. The fact that these opposite concepts have to be reconciled in order to solve any optimization problem gave birth to the so-called exploration/exploitation trade-off. The optimal trade-off being problem dependent, it is important to devise methods able to tune the balance between them. In EA, the influence of exploitation can be linked to the convergence of the population. If the influence of exploitation is too high, the algorithm cannot escape the local optimum basin it is currently exploring, and it converges prematurely. On the other hand, if the influence of exploitation is too low, the algorithm randomly explores the search space without going deep enough into the optima basins. Both of these extreme behaviors are unwanted and lead to poor performance. If we come back to the evolutionary metaphor, the balance between exploration and exploitation can be seen as the selective pressure exerted on individuals competing for survival. When the selective pressure is high, only individuals expressing specific vital genetic traits survive and reproduce. In this scenario the diversity in the population is reduced, which limits the exploration of the search space by recombination of the individuals, and favors exploitation of specific attraction basins. When the selective pressure is low, there are no vital genetic traits. The lack of constraints on the genes of the individuals allows them to freely explore the fitness landscape. Many different models have been proposed in order to achieve optimal trade-offs. In the island model, solutions are separated into subpopulations. This separation allows an algorithm to follow several search trajectories in parallel, and solutions can be periodically traded between islands (Whitley *et al.*, 1998). In the cellular model, solutions are spatially distributed on a grid and can only interact for crossover with their neighbors (Alba and Dorronsoro, 2008). This spatial arrangement of solutions allows one to tune the balance between exploration and

exploitation by playing on the size and the definition of neighborhoods (Simoncini *et al.*, 2006, 2009). Besides these generic schemes, problem specific heuristics can be designed in order to adapt to the search space properties and provide efficient sampling. The protein structure prediction problem, with a huge search space and rugged landscape, is an example of an important application for which many heuristics have been designed looking for the best trade-off between exploration and exploitation.

Application to Fragment-Based Protein Structure Prediction

This section uses EdaFold as an example of a population-based sampling algorithm as it is applied to protein structure prediction. EdaFold is an Estimation of Distribution Algorithm (EDA) built on top of the Rosetta fragment-based *ab initio* protocol. After a brief introduction to fragment-based protein structure prediction, and a presentation of the Rosetta modeling software, the EDA mechanism implemented in EdaFold will be described and a practical use case discussed.

Fragment-Based Protein Structure Prediction

Proteins are chains of amino acids connected by peptide bonds. A protein chain naturally folds into a three-dimensional structure known to be responsible for its role or function. Each amino acid residue in a protein chain has three angular degrees of freedom on its main chain: the ϕ , ψ and ω angles. These angles determine the global fold of a protein. The ω angle is highly constrained by the planar nature of the peptide bond, and is therefore often neglected by protein structure prediction methods, which focus on the values of angles ϕ and ψ (see Fig. 2). For a protein composed of 100 residues, assuming we only consider 180 discrete angular values for ϕ and ψ , the size of the search space is about 10^{255} .

The principle of fragment-based protein structure prediction is to discretize and diminish the size of the search space by assembling small protein fragments together instead of considering all possible degrees of freedom induced by the protein main chain torsion angles. Besides reducing the size of the search space, fragment-based approaches have the advantage of extracting structural information from known protein structures that locally resemble the target protein. Since the relationship between sequence and structure is well known, the idea makes sense and has encountered a lot of success in the last two decades. Fragment-based methods drew the attention of researchers after the results obtained by David Baker's group during the CASP protein structure prediction blind challenge (Bradley *et al.*, 2005a).

The fragment-based approach implemented in Rosetta consists of two phases: fragment assembly and refinement. The fragment assembly phase uses a coarse-grained representation of proteins where the residue side chains are replaced by a center of mass centroid. It is decomposed in 4 stages. In the first three stages, fragments of length 9 (9-mers) are used. The last stage uses fragments of length 3 (3-mers). The fragments are overlapping: the 9-mers (respectively 3-mers) library contains 25 (respectively 200) fragments for each residue from 1 to N-8 (respectively N-2) where N is the length of the protein sequence. What differentiates the stages is the score function that is used. The score function becomes more and more complex as the search proceeds, and the number of fragment insertion trials increases. The optimization is handled by a Monte Carlo simulated annealing process, which randomly selects a position in the protein sequence, randomly selects a fragment from the library, and evaluates the energy variation induced by the insertion of the fragment. The fragment insertion is accepted with probability $\min\left(1, e^{-\frac{E'-E}{T}}\right)$ where E' is the energy of the model after fragment insertion, E the energy of the model before fragment insertion, and T a temperature parameter. Using this technique, called the Metropolis criterion (Hastings, 1970), the fragment insertion is

Fig. 2 Amino acid residues in a protein and main chain ϕ , ψ and ω torsion angles. One amino acid is shaded in blue. The R group is the side chain which differentiates the amino acids.

automatically accepted if the new energy is better. Otherwise, it is accepted with a probability that depends on the temperature and the energy difference. The temperature parameter allows one to calibrate which models that worsen the energy will be accepted. T gradually decreases over the course of the simulation. This biases the process toward exploration in the early (high T) stages, and toward exploitation in the late (low T) stages. After the fragment insertion phase, the resolution of the protein models is switched to an all-atom representation for the refinement phase. This phase, known as the Relax protocol, alternates between gradient descent minimization and residue side chain packing evaluation.

Due to the size of the search space and the number of local minima, many independent simulated annealing trajectories (or runs) have to be performed in order to have a chance of finding a model with the correct fold. While they may be globally wrong, many of the models that are produced contain correct and useful local topologies that favorably contribute to the total energy of the protein. Identifying and exploiting this information is the driving idea behind the population-based sampling method, EdaFold, and its latest implementation, EdaRose.

EdaRose

The EDA algorithm implemented in EdaRose adjusts the probability distribution over the fragment libraries in order to guide the search toward native-like protein models. This probability distribution is typically uniform in single solution simulated annealing, such as in Rosetta, where each fragment has the same probability of being selected during the fragment assembly phase. EdaRose modifies the probability distributions empirically, accordingly to the observed frequency of the fragments in a pool of pre-selected models. The EDA only changes the 9-mer fragment assembly phase. The final, and much shorter, 3-mer assembly phase remains unchanged. The search space sampling method implemented in EdaRose does not rely solely on the EDA: it includes a local search method as well. EdaRose can thus also be classified as a memetic algorithm since it combines an EDA with a local search method, even though it has many unique properties which will be described below. EdaRose is built on top of Rosetta and uses its protein representation and simulated annealing method (Simoncini *et al.*, 2017).

Protocol design particularities

Before presenting the algorithm, we focus on some unique characteristics of EdaRose which are, to some extent, dictated by the application to protein structure prediction. Some of these particularities are related to the representation of protein models and the way they are constructed, some others are related to the search dynamics.

Indirect representation of solutions. The first particularity of EdaRose is that the EDA does not try to capture the probability distribution describing the solutions: it is intended to capture the probability distribution over the fragments that are used to build the solutions. The data contained in the fragments are not 3D coordinates of amino acid residues, but ϕ and ψ torsion angles, which are sufficient to determine the fold of a protein. The 3D Cartesian coordinates can be easily obtained from the torsion angle values. Since the fragments overlap, the order in which they are inserted has an influence on the fold of the final model: the insertion of a fragment that partially overlaps another, previously inserted, fragment will overwrite pre-existing torsion angle data, and modify the global fold of the model. In EdaRose, each model keeps track of the list of fragments that were used to build it, in order to transmit this information to the EDA. However, the information about the order in which the fragments were inserted is lost. This particularity can lead to extreme cases where the distribution is a Dirac delta function that assigns a probability of 1 to a single value and 0 to all other values. In such a case, there should be a unique solution, but the actual number of solutions is factorial (W) where W is the number of fragment windows. This is due to the fact that the EDA acts on an indirect representation of the solutions, the fragments, and because the final model fold relies on the order in which fragments were inserted.

EDA and local search interplay. Another particularity of EdaRose is the interlacing of the EDA and the simulated annealing, which is used as a local search method. In a standard scheme, solutions would be generated based on the EDA, and would then be used as starting points in order to run simulated annealing search trajectories. Instead, EdaRose uses the EDA to directly bias the search trajectories performed by the simulated annealing algorithm. The solutions are not generated with the EDA but with the local search method, which uses the EDA to decide which move to make, i.e., which fragment to insert in the protein model. At the end of an iteration, the solutions are gathered and examined in order to refine the probability distribution used by the simulated annealing. Even if this scheme is not specific to protein structure prediction, and could be implemented for any application, it facilitates the integration of EdaRose in the Rosetta macromolecular modeling software.

Algorithm

Algorithm 5 presents an outline of EdaRose as implemented on top of Rosetta. The algorithm takes as inputs the sequence of the protein which is to be modeled and a desired number of iterations. The EDA estimates the probability distribution over the fragments once per iteration. It is initialized with a uniform distribution (line 4) and a first batch of solutions is generated (lines 5 and 6). The *fast_relax* function is an implementation of the Rosetta Relax protocol that minimizes the energy of the model in the all-atom representation, whereas the *simulated_annealing* function performs fragment insertion using a coarse-grained representation. The relaxation in all-atom representation is optional and can be skipped. The iterative process then begins with the selection of the models (line 8), which will be used by the EDA in order to refine the probability distribution (line 9). The model selection is a crucial part of the algorithm, and will be discussed in more detail in the following section. Models are then generated using fragment insertion with the EDA-based simulated annealing, and an optional all-atom relaxation of the models (lines 10

and 11). Contrary to most EA, the population of solutions is not replaced at the end of an iteration. All the solutions are kept in the population which grows linearly from the first to the last iteration. This particular behavior was adopted mainly because of the uncertainty associated with the inaccuracy of the objective function. As is the case for many practical real-world applications, the objective function is empirical and there is no guarantee that its global minimum corresponds to a protein model with the correct fold. It is thus wiser to save all models, and to implement a post-filtering strategy in order to identify the native-like models in the solutions produced throughout the entire process. The main phases of the algorithm are recapitulated in Fig. 3: fragment assembly, model relaxation, model selection, and estimation of distribution.

Algorithm 5 EdaRose

```

1: input :  $s$  {sequence of the target protein}
2: input :  $n$  {number of iterations}
3: output :  $p$  {set of potential solutions}
4:  $pmf \leftarrow \text{init\_with\_uniform\_distributions}()$ 
5:  $p \leftarrow \text{simulated\_annealing}(s, pmf)$ 
6:  $p \leftarrow \text{fast\_relax}(p)$  {optional}
7: for  $i$  in  $[1..n - 1]$  do
8:    $sub_p \leftarrow \text{select\_solutions}(p)$ 
9:    $pmf \leftarrow \text{estimate\_pmf}(sub_p)$ 
10:   $p \leftarrow p \cup \text{simulated\_annealing}(s, pmf)$ 
11:   $p \leftarrow \text{fast\_relax}(p)$  {optional}
12: end for
13: return  $p$ 
  
```

The selection of solutions plays a central role in determining the diversity of the population and the quality of the estimation of the probability distribution. Protein structure prediction offers many possibilities for the design of selection strategies. Two strategies are currently implemented in EdaRose: energy selection, and energy-based clustering selection. The first strategy selects protein models according to the evaluation of their energy as calculated by the scoring function. A parameter controls the proportion of the population that will be retained for the estimation of the distribution over the fragments at each iteration. The

Fig. 3 Illustration of the four main steps of EdaRose. The iterative process starts with fragment assembly of protein models. The models are then relaxed in all-atom representation. Representatives are then selected and exploited in order to refine the probability distribution over the fragments used during assembly.

second strategy uses a hierarchical clustering approach to select protein models that cover large regions of the search space. The energy being an important selection criterion, it is used to guide the clustering algorithm. This strategy is outlined in [Algorithm 6](#). The desired number of clusters and the clustering radius (the maximum distance between a cluster center and a member of the same cluster) have to be specified. By default, the number of clusters is set to 100 and the clustering radius to 4 Å RMSD. The algorithm selects the lowest energy solution from the set of potential solutions as a cluster center (line 7), and adds it to the set of selected models (line 8). At the beginning of the process, the set of potential solutions contains all of the models that were produced during one iteration of EdaRose. Then, the algorithm finds all the solutions belonging to the same cluster and removes them from the set of potential solutions (line 9). This procedure is repeated until the desired number of solutions (i.e., number of clusters) is reached (line 6). Energy-based clustering is the default selection method in EdaRose. The ability to customize selection methods is an attractive feature of population-based sampling algorithms because it offers a way to control the search dynamics and the convergence rate of the algorithm. Furthermore, it allows one to introduce problem specific information that may be critical for the success of the sampling process. For protein structure prediction, many features could be exploited in order to design efficient selection methods. For example, residue contacts derived from co-evolutionary analysis could be used by a selection method in order to favor models that satisfy those contact restraints.

Algorithm 6 Model selection scheme for energy-based clustering.

```

1: input :  $P$  {set of potential solutions}
2: input :  $nbclusters$  {number of clusters to extract}
3: input :  $d$  {clustering radius}
4: output :  $M$  {set of selected protein models}
5:  $M \leftarrow \emptyset$ 
6: for  $i$  in  $[1..nbclusters]$  do
7:    $m \leftarrow find\_lowest\_energy\_model(P)$ 
8:    $M \leftarrow M \cup m$ 
9:    $P \leftarrow remove\_cluster(P, m, d)$ 
10: end for
11: return  $M$ 

```

Test Case

In this section, we present the whole process of a population-based protein structure prediction with EdaRose: from protein fragment library creation to protein model generation and analysis. In this example, we will try to predict the structure of an IgG-binding B1 domain of protein L (pdb code 1HZ5) ([O'Neill et al., 2001](#)). We will go through the whole process step by step.

Fragment library creation. The first step is to generate the fragment libraries. Two libraries need to be generated: a library of 9-mers and a library of 3-mers. The simplest way to do this is to use the Robetta server online ([Kim et al., 2004](#)): <http://rosetta.bakerlab.org/>. In order to generate the fragment libraries, you will need to submit a fragment library task: log in, enter a target name and copy/paste the fasta sequence of the target protein (1hz5 in our case). If you want to test the reliability of EdaRose ignoring the homologous structures in the PDB, remember to tick the *exclude homologues* box. Once the job is completed, download the two fragment libraries (the first two files in the results) and rename them to *1hz5.frag3* and *1hz5.frag9*.

Parameters setting and command line. The main parameters of EdaRose are listed in [Table 2](#). Some of these parameters are specific to EdaRose: the number of iterations, the damping factor of the EDA (which controls the convergence speed) and parameters relative to the selection method. The other parameters are mandatory Rosetta input files and options. Many other Rosetta options such as the use of constraints or symmetry are compatible with EdaRose, please refer to the Rosetta documentation (<https://www.rosettacommons.org/>) for more details. A typical EdaRose command line would be:

```

mpirun -np NP ./EdaRose -in:file:fasta 1hz5.fasta -in:file:frag3 1hz5.frag3
-in:file:frag9 1hz5.frag9 -eda:nbiterations 6 -eda:popthreshold 0.6
-nstruct 60000 -out:pdb

```

where NP is the number of cores used by Open MPI, an open source implementation of the Message Passing standard for parallel computing, which is mandatory. With the default setting, no all-atom relaxation will be performed and the predicted models will be produced in the coarse-grain representation. All-atom relaxation can be included in the process with the appropriate option (see [Table 2](#)), even though it is a time consuming step. Another possibility is to use the Rosetta relax application as a post-processing step in order to relax only a fraction of the best energy models (see the Rosetta documentation at https://www.rosettacommons.org/docs/latest/application_documentation/structure_prediction/relax for more details about Rosetta relax protocol). In this example, we opted for the latter solution and relaxed the best 1000 energy models. For this test-case, the computation time was roughly 4 h, using 100 cores for the prediction of 60,000 models, and 30 min for the relaxation of 1000 models

Table 2 EdaRose options. Parameters prefixed by *eda* are specific to EdaRose

-eda:nb_iterations	Number of iterations
-eda:distrib_k	EDA conservation rate
-eda:clustering	clustering-based model selection (default: true)
-eda:pop_threshold	Top ranked model threshold for energy-based selection
-in:file:fasta	target sequence in fasta format
-in:file:frag9	9-mers fragments library file
-in:file:frag3	3-mers fragments library file
-nstruct	Total number of models
-relax:fast	Specify this option to include model relaxation

The other ones are mandatory Rosetta options.

Fig. 4 Protein cartoon model generated with EdaRose in red superimposed on the target native structure (pdb code 1hz5) in gray. The ribbons represent a smooth curve fit through the C_{α} carbons of the backbone; the arrows represent beta strands; the ribbons without arrowheads indicate alpha helices, and irregular regions are shown as narrow tubes. The protein model has the second best energy in the population of models and has a root mean square deviation to the native structure of 3 Å.

using 20 cores. The number of models can be adapted to the computational power available, keeping in mind that the size of the population plays an important role in the performance of the EDA.

Results analysis. The computational job produces a *score file* (score.fsc by default) containing the breakdown of the energy terms and the total score of each model produced during the run. With the flag *out:pdb* on the command line, each model will be output in PDB format. In our example, we generated 60,000 models in 6 iterations (10,000 per iteration) and relaxed the top 1000 lowest energy models using the all-atom representation. Fig. 4 shows the most accurate model, in terms of root mean square deviation to the native structure, out of the 5 lowest energy models (please note that the all-atom relaxation re-ranks the models energy-wise). When no homologous protein can be identified in the PDB, a prediction run can be considered successful if there is at least one accurate model out of the five lowest energy models. This quality criterion is widely accepted: during the biennial blind protein structure prediction contest, CASP, the participants are allowed to send five models per target. In addition to the energy of models, several options exist for assessing the quality of the predictions. The quality assessment of protein models is a research field on its own, and the most popular methods employ clustering and pairwise analysis (consensus scores) in order to re-rank the protein models.

Conclusion

Protein structure prediction remains an open problem of great importance in structural biology. The huge size of the search space, and the ruggedness of the fitness landscape, make it a challenging NP-hard problem, even for modern computer hardware and state-of-the-art optimization algorithms. Popular methods, such as Rosetta, need to generate a substantial number of protein models due to the typically large number of local minima. In this context, and with the democratization of parallel computer architectures, population-based meta-heuristics such as evolutionary algorithms represent an interesting alternative. Population-based methods have the ability of sharing information between the solutions. This ability provides multiple possibilities: mainly, it allows the steering of the search by extracting and exploiting information from good solutions, and it enhances the exploration of the search space by promoting diversity in the population. Of course, exploitation of good solutions and exploration of the

search space are in competition during a search trajectory. Population-based methods can be tuned and customized in order to adjust the balance between exploitation and exploration. The ideal balance is problem dependent and expert knowledge is often needed in order to improve the efficiency of the algorithms. Evolutionary algorithms are highly customizable at many different levels, from the selection of solutions to the stochastic operators, and even the population replacement strategy. Many features and useful information can be extracted from proteins and used to make the protein structure prediction problem highly compatible with population-based methods. EdaRose is an estimation of distribution algorithm built on top of Rosetta. It has been customized in order to exploit some information about the structure of the protein models. Many research studies put in evidence the benefits of population-based methods in terms of sampling and performance compared to single solution methods. The introduction of additional expert knowledge, or the design of novel concerted search strategies, would probably further improve the gain in performance, taking advantage of the flexibility of population-based sampling methods.

Ontology: Introduction

Gianluigi Greco and Marco Manna, University of Calabria, Cosenza, Italy

Francesco Ricca, University of Calabria, Rende, Italy

© 2019 Elsevier Inc. All rights reserved.

Overview

Ontology – from the Greek ὄν, genitive ὄντος: *of being* (present participle of ἔIMI: *to be*), and ΛΟΓΙΑ for ΛΟΓΟΣ: *science, study, theory* – is the study of the nature of being, existence, or reality in general and of its basic categories and their relations.

Moving from the above original definition, nowadays, an ontology is pragmatically viewed in computer science as structure that specifies a conceptualization or, more accurately, *a specification of a shared conceptualization of a domain* (Thomas, 1993). In fact, this term is very often used to refer to a wide range of different formal representations, including taxonomies, hierarchical terminology vocabularies or detailed logical theories describing a domain (Noy and Klein, 2004). Therefore, providing the reader with an accurate and univocally determined definition is rather difficult (Thomas, 1993, 1995; Guarino, 1998). For the sake of concreteness and by following a rather accepted abstract formalization (de Bruijn et al., 2004; Predoiu et al., 2005), we present here an ontology as a quadruple $\mathcal{O} = \langle C, R, \iota, \xi \rangle$, where C is a set of concepts, R is a set of relations, ι is a set of instances and ξ is a set of axioms. In fact, some authors prefer not to include ι in $\mathcal{O}$ and to talk about a *knowledge base* when an ontology (with no instance) is paired with instances.

A concept in an ontology is a category of real or virtual objects of interest, which are the instances. Relations specify how different concepts (or instances) are interconnected, and axioms are formulae that allow to further define dependencies between all mentioned ontology entities. Moreover, the sets C and ι are not necessarily disjoint (for instance, the same term can denote both a class and an instance), although it is often required that this property holds. Moreover, in an ontology, concepts are usually organized in a subclass hierarchy, through the *is-a* (or sub-concept-of) relationship. More general concepts reside higher in the hierarchy. Such a special kind of relationship is called *taxonomic*, as well as the *part-of* relationship, which both define hierarchies of concepts.

The specification of an ontology is usually done by using a formal knowledge representation language. This means that concepts, relations, instances, and axioms are specified in some logical language.

As an example, by adopting a first-order like abstract syntax, consider the ontology $\mathcal{O} = \langle C, R, \iota, \xi \rangle$ where $C = \{Exam, Student, Person, Number\}$, $R = \{pass\}$, $\iota = \{Exam(e), Student(s_1), Student(s_2), Number(1), \dots, Number(100), pass(s_1, e, 18), pass(s_2, e, 30)\}$, and finally $\xi = \{pass(S, E, G) \wedge G < 18 \rightarrow \perp, pass(S, E, G) \wedge G > 30 \rightarrow \perp, pass(S, E, g) \wedge \neg Number(g) \rightarrow \perp, pass(S, E, G) \rightarrow Student(S), pass(S, E, G) \wedge \neg Exam(E) \rightarrow \perp, Student(S) \rightarrow Person(S)\}$.

Note that, in this example, the ontology states that e is an exam, that s_1 and s_2 are students, that 1...100 are numbers, that s_1 passes exam e with grade 18, and that s_2 passes exam e with grade 30. Moreover, it formalizes (via ξ the facts that the grade of an exam is a number that may range from 18 to 30, that if someone passes an exam then he/she is a student, that nobody can pass something which is not an exam, and that every student is a person.

An ontology specification should allow one to model the definitions of terms and relations holding in a domain. For this purpose, several ontology specification languages have been proposed in the literature. These languages feature different syntactic, semantic, and expressivity properties. The choice of the most appropriate ontology language depends on the intrinsic characteristic of the target domain, and on the area of application, that is, it depends on the *ontological commitments* (Thomas, 1993) of those who are expected to use the specification.

In the following section, some basic ontology specification languages are surveyed. Notably, some of them have been defined for general knowledge representation tasks, others have been conceived to support the development of ontologies for the semantic Web, and some others were intended for developing enterprise knowledge bases. In the rest of the article, we then overview the most important steps for designing an ontology (see Section Ontology Design), we discuss the tools available to develop and manage ontologies (see Section Tools for Ontology Management), and we present some examples of real ontologies of interest in biological domains (see Section Ontologies in Bioinformatics and Biology).

Ontology Languages

In this section, we mention some ontology specification languages appeared in the recent literature (Calì et al., 2009; Corcho and Gómez-Pérez, 2000; Ricca and Leone, 2007): F-Logic, RDF, OWL, OntoDLP, and Datalog[±].

F-Logic

Frame Logic is a popular logic-based object-oriented language which includes most aspects of object-oriented and frame-based languages (Kifer et al., 1995). It was conceived as a language for intelligent information systems based on the logic programming paradigm. A main implementation of F-logic is the Flora-2 system (Yang et al., 2003) which is devoted to Semantic Web reasoning tasks. Flora-2 integrates F-Logic with other novel formalisms such as HiLog (Chen et al., 1993) (a logical formalism that provides

higher-order and meta-programming features in a computationally tractable first-order setting) and Transaction Logic (Bonner and Kifer, 1994) (that provides a logical foundation for state changes and side effects in a logic programming language).

RDF

A number of formalisms for specifying ontologies have been originally proposed by the World Wide Web Consortium (W3C), in particular, RDF and RDFS. The *Resource Description Framework* (RDF) (Ralph, 1998; W3C, 2006) is a knowledge representation language for the Semantic Web. It is a simple assertional logical language which allows for the specification of binary properties expressing that a resource (entity in the Semantic Web) is related to another entity or to a value. RDF has been extended with a basic type system; the resulting language is called RDF Vocabulary Description Language (RDF Schema or RDFS). RDFS introduces the notions of class and property, and provides mechanisms for specifying class hierarchies, property hierarchies, and for defining domains and ranges of properties. Basically, RDF(S) allows for expressing knowledge about the resources (identified via URI), and features a rich data-type library.

OWL

The *Ontology Web Language* (Smith et al., 2004) is an ontology representation language built on top of RDFS. Ontologies defined in this language consist of concepts (or classes) and roles (binary relations also called class properties). OWL has a logic-based semantics and, in general, it allows us to express complex statements about the domain of discourse (OWL is undecidable in general) (Smith et al., 2004). More precisely, Description Logics (DLs) (Baader et al., 2003) represent the key logics underpinning OWL. The largest decidable subset of OWL, called OWL-DL, basically coincides with $\mathcal{SHOIN}(\mathcal{D})$, one of the most expressive Description Logics (Baader et al., 2007). Finally, OWL and DLs are based on classical logic; in fact, there is a direct mapping from $\mathcal{SHOIN}(\mathcal{D})$ to first-order logic (FOL).

OntoDLP

This is a language based on Disjunctive Logic Programming (DLP) and extended with object-oriented features (Ricca and Leone, 2007). In particular, DLP is an advanced formalism for Knowledge Representation and Reasoning expressing all problems belonging to the complexity class $(\Sigma)_2^P$ – the class of all decision problems solvable in nondeterministic polynomial time by a Turing machine with an oracle in NP. In fact, the language OntoDLP includes, besides the concept of *relation*, the object-oriented notions of *class*, *object* (class instance), *object-identity*, *complex object*, *(multiple) inheritance*, and the concept of modular programming by means of *reasoning modules*.

Datalog[±]

This is a family of knowledge representation languages to specify ontologies (Calì et al., 2009), whose intent is to collect all expressive extensions of Datalog which are based on existential quantification, equality-generating dependencies, negative constraints, negation, and disjunction. In particular, the “plus” symbol refers to any possible combination of these extensions, while the “minus” one imposes at least decidability of the main reasoning tasks (Calì et al., 2012a,b, 2013; Fagin et al., 2005; Leone et al., 2012). Originally, this family was introduced with the aim of “closing the gap between the Semantic Web and databases” (Calì et al., 2012a) to provide the *Web of Data* with scalable formalisms that can benefit from existing database technologies. And, in fact, it generalizes well-known subfamilies of Description Logics – such as $\mathcal{EL}$ (Brandt, 2004) and *DL-Lite* (Artale et al., 2009) – collecting the basic tractable languages in the context of the Semantic Web and databases. Currently, Datalog[±] has evolved as a major paradigm and an active field of research.

Ontology Design

The design of an ontology is a complex process. Therefore, it comes with no surprise that an entire area of computer science is devoted to study and define methods and methodologies for building ontologies (Thomas, 1993). By abstracting from the specific proposals in the literature, we can see that the development of an ontology takes place by considering some fundamental steps:

- Analysis of the domain of interest, where all the necessary information regarding domain and entities is collected. All the information gathered must be translated into a common language chosen for that particular ontology. The formalization process must be carried out by adhering to the domain and by taking into account the purpose of ontology and the users who will handle it;
- Reuse of existing resources, where parts of ontologies already available at hand have to be identified for possible reuse. This step guarantees benefits both in terms of development and time of implementation;
- Planning the conceptual structure of the domain, which corresponds to defining its concepts and properties and the various relationships between them. This step is crucial for developing a flat glossary and elaborating a glossary structure;

- Coherence and consistency checking, which means verifying any semantic, logical and syntactic inconsistencies.

By looking at the above tasks, the design of an ontology can be approached in different ways and the choice of the most appropriate one depends on the characteristics of the domain that has to be modeled. By speaking in general terms, there are three main approaches: bottom-up, top-down and mixed:

- Bottom-Up Approach. In this type of approach, we first define the most specific concepts and then move to characterize the more generic ones. This approach is performed to a degree of generalization and abstraction that allows us to achieve the purposes for which the ontology is designed. As a result, concepts are represented according to a certain hierarchy.
- Top-Down Approach. In this case, we first identify the most general concepts and then move to the more specific ones, reaching an appropriate level for the purposes of ontology. Even in this case, concepts are represented by a taxonomy and their specialization must respect the purpose of ontology.
- Mixed approach. In this type of approach, we first identify all the concepts that are considered important for the domain to be represented, then we look for the hierarchical ties that bind the concepts to organize them from the most general to the most specific.

No matter of the specific design approach being selected, an ontology should be designed to meet some desirable criteria and the ontology designer is in charge to accept trade-offs among them (Thomas, 1993) in order to obtain the best results for a particular application. A few desiderata for ontologies are summarized in the following. First, an ontology should be *clear*, that is, it should be objective and communicate the intended meaning of defined terms. This should be obtained by properly constraining the possible interpretations for the defined terms. An ontology should be *coherent*, that is, the entire specification should be logically consistent, so that it will allow to perform correct inferences and reasonings on the knowledge it specifies. An ontology should be *extensible*, that is, it should be designed to be easily extended with new terms that will be required by future applications. Extensions should be possible by reusing the existing vocabulary. An ontology designed for knowledge-sharing should minimize the *encoding bias*, that is, it should not depend on a particular encoding or notation, in order to maximize usability in different systems and styles of representation. Moreover, a general purpose ontology should have *minimal ontological commitment*, that is, it should make as few claims as possible about the world being modeled and provide definitions for those terms that are essential to model the target domain.

Tools for Ontology Management

Numerous tools have been developed in the past few years, both in the university and commercial fields, in order to provide support for the specification and manipulation of ontologies. The use of such tools that have advanced graphical capabilities is essential for applying ontologies in real-world applications, in particular because users are very often not expert about specific linguistic formalisms for the specification of ontologies.

Various kinds of tools have been developed to cope with various developmental requirements and ontologies. A classification can be made based on the particular use for which such tools have been conceived and developed:

- Tools for the development of ontologies. This category includes all the tools that can be used to build new ontologies from scratch or reuse pre-existing ontologies;
- Tools for integrating and fusing ontologies. These are tools born to deal with the integration of different ontologies concerning the same domain;
- Tools for evaluating ontologies. This category refers to the tools that must ensure the quality of the ontologies and their technologies;
- Ontological-based annotation tools. These tools are designed to allow users to insert and maintain semi-automatic markup-based ontologies (especially) on web pages;
- Tools for querying and storing ontologies. These tools have been designed to simplify the use and the querying of ontologies;
- Tools for learning ontologies. These tools are capable of deriving, semi-automatically, ontologies (usually) from text written in natural language.

For each of the above categories, currently available ontology tools are rather numerous, even though their usage is limited by a number of issues limiting their diffusion, especially in the commercial sphere. Very often, in fact, these tools are complex and are not accompanied by appropriate documentation. Another crucial issue in the use of ontology tools is the need to combine different solutions that are not conceived to natively cooperate with each other. At present, there is no ontology management tool that is a complete platform for ontologies management and that, therefore, can offer in one environment all the features needed to manage ontologies: specifying, manipulating, storing and query.

Among the available solutions, Protégé (Noy *et al.*, 2001), developed at the University of Stanford, is one of the most well known and used. It provides a graphical and interactive editor for ontology design and acquisition of knowledge. The tools has been designed to help knowledge engineers and domain experts to realize knowledge management goals. Ontologists can access information quickly whenever they need it and can modify ontology directly by navigating the tree that represents it. The knowledge model used by Protégé is compatible with current standard and one of the major advantages of its architecture is that it

guarantees an open and modular environment. Indeed, programmers can add new features simply by creating the appropriate plug-ins. Protégé comes equipped with libraries containing display plug-ins, knowledge-based inference engines (to verify first-order logic constraints), and methods to capture information from remote and heterogeneous resources.

In Protégé, a class can be concrete or abstract. In the latter case, the class serves to convey a series of attributes possessed by different classes, but it admits no instances. Protégé offers a panel that manages the building part of the classes and defines the relationships between the concepts that are part of it. In this panel, users can: define the taxonomy of the ontology by pointing out what are the elements of their hierarchy of concepts and relationships (represented by a tree); manage the inheritance relationship between concepts, allowing users to add or remove relatives to a tree node; view and manage attributes related to the selected concept on the tree; managing individuals (instances). Moreover, Protégé implements a panel where conceptual instances can be defined and managed. In this case, the panel is divided into sections that allow: to explore the defined taxonomy; to handle instances linked to the selected concept; to view information related to a single instance. Finally, Protégé supports an ontology query management mechanism. A query can be used to verify, for example, existing relationships between defined concepts, or links to instances.

Ontologies in Bioinformatics and Biology

The use of ontologies in bioinformatics and biology has a long tradition. Indeed, this domain can be considered as one of the prototypical examples for the application of ontologies to concrete real-worlds problems. In the following, we mention some well-known projects that are aimed at developing ontologies in this context as well as some pointers for obtaining these ontologies.

The Gene Ontology (GO) (see Relevant Websites section) is by far the most widely used ontology in biology. GO defines biological processes, molecular functions and cell components. The GO vocabulary is designed to be general and applicable from prokaryotes to multicellular organisms. The vocabulary is organized in three orthogonal hierarchies representing gene product properties: (i) Cellular Component, modeling the parts of a cell or its extracellular environment; (ii) Molecular Function, modeling the elemental activities of a gene product at the molecular level; (iii) Biological Process, modeling operations or sets of molecular events related to the functioning of integrated living units: cells, tissues, organs, and organisms. GO is linked to a database of hundred of thousands genes of animals, plants, fungi, bacteria and viruses. The user can find, for each gene, detailed information about the role it plays and its products.

The Systems Biology Ontology (SBO) is a set of controlled, relational vocabularies of terms commonly used in Systems Biology (see Relevant Websites section). It defines reaction participants roles, quantitative parameters, mathematical expressions describing the system, the nature of the entities, the type of interaction. The aim of SBO is to annotate the results of biochemical experiments in order to facilitate their efficient reuse.

The Ontology of Physics for Biology (OPB) is a reference ontology of classical physics as applied to the dynamics of biological systems (see Relevant Websites section). It is designed to cover multiple physical domains at different structural scales, and to support the study and analysis of biological organisms.

A hub collecting references to many ontologies describing the domains of biology is provided by the Open Biomedical Ontologies (OBO) Foundry (see Relevant Websites section), a network of ontology developers that are committed to the development of a family of interoperable ontologies that are both logically well-formed and scientifically accurate.

Closing Remarks

In this article, we provided an overview of ontologies in computer science. In this area, an ontology is a formal way of representing knowledge in which concepts are described both by their meaning and their relationship with each other. A key component in an ontology specification is the selection of a formal language to model the definitions of the terms and the relations that hold in the given domain. For this purpose, we reviewed several languages featuring different syntactic, semantic, and expressivity properties. For readers interested in ontology engineering, we have discussed the main approaches for designing an ontology, and listed some desirable properties that an ontology is expected to enjoy. Finally, we provided links to existing ontologies that have been developed in the field of biology, in order to provide the reader with references to concrete ontologies that are currently used in practical applications.

Ontology: Definition Languages

Valeria Fionda and Giuseppe Pirrò, University of Calabria, Rende, Italy and ICAR-CNR, Rende, Italy

Introduction

Ontologies are formal artifacts that allow to gain a shared understanding of a particular domain of interest. Ontologies model knowledge about individuals, their attributes, and their relationships by providing a level of abstraction that goes beyond classical data models (e.g., the relational model). Indeed, one of the main advantages of ontologies is their ability to provide abstraction from data structures, implementation strategies and lower-level data models. Ontologies are also a useful support for integrating heterogeneous knowledge bases, thus enabling interoperability among different data providers and applications. This is particularly relevant in the context of life sciences where different ontologies are often used by biologists to model overlapping knowledge domains that characterize, for instance, experiments. From a concrete point of view, the definition of ontologies is supported by a variety of ontology languages with different levels of expressiveness; expressiveness refer to the capability of a language to model a particular aspect. Ontology definition languages, indeed, also allow to specify semantic rules to reason about the knowledge encoded in the ontology.

The massive amount of data characterizing today's applications calls for automatic techniques that can process and interpret ontologies. In other words, ontologies need to be interpreted and processed by machines. This will foster the possibility to perform quick and complex types of inferences that are helpful in a variety of tasks, including search and knowledge base integration. A typical context where inference is of utmost importance is the detection (and resolution) of knowledge base inconsistencies. A key ingredient toward the definition of inferences is the definition of logic-based semantics for ontologies.

In this article we provide an overview of some ontology definition languages that have been defined under the umbrella of the W3C consortium. We will focus our attention on three languages: the Resource Description Framework (RDF), RDF Schema (RDFS) and the Ontology Web Language (OWL).

While the RDF language is mostly a data-model for expressing facts, i.e. it does not bring (much) semantics or meaning to such facts, RDFS and OWL allow to make claims about things described by an RDF document. These formal languages (RDFS is quite simple, whereas OWL is much richer) offer a meta-vocabulary with well-defined semantics to express constraints.

Resource Description Framework

The Resource Description Framework (RDF) (Consortium *et al.*, 2014) is a data model to represent information. In particular, RDF has been proposed with the aim of describing annotations (facts) about Web resources. The abstract RDF syntax (Consortium *et al.*, 2014) has several concrete implementations such as Turtle, (Beckett *et al.*, 2014) n-triples (Beckett, 2014) or XML (Gandon and Schreiber, 2014). For sake of readability, in the examples of this section we will use the Turtle syntax. In the last few years there have been several efforts to define extensions of RDF (e.g. for dealing with time (Gutierrez *et al.*, 2007) or trust values (Fionda and Greco, 2015)). Web resources can be referenced by using RDF terms.

Definition 1 (RDF terms). *The set of RDF terms is the union of three disjoint sets: the set of all Uniform Resource Identifiers (URIs) ($\mathcal{U}$), the set of all literals ($\mathcal{L}$) and the set of all blank nodes ($\mathcal{B}$).*

URIs are global identifiers. For example, <http://dbpedia.org/resource/Mouse> is used to identify the mouse mammal specie in the DBpedia (DBpedia is a crowd-sourced community effort to express Wikipedia information into RDF) knowledge base. (Lehmann *et al.*, 2015) Importantly, RDF does not take the Unique Name Assumption; this means that two different terms can refer to the same entity. For example, the URI <http://rdf.freebase.com/ns/m.04rmv> is used by Freebase (another data provider) to identify the mouse mammal specie. To avoid to write full URI strings, prefixes can be used. For example, by using the prefix `dbr` to denote the DBpedia knowledge base (i.e., @prefix dbr: <http://dbpedia.org/resource/>) we can simply write `dbr:Mouse`. Literals are a set of lexical values such as strings, numbers, and dates. Literals can be of two types: *lexical forms* that is a plain string (e.g. "Mouse") or *datatype IRI* that consist of a lexical string and a datatype (e.g., "1"^^xs: integer). Blank Nodes are defined as existential variables and denote some resource whose reference is not made explicit. Blank nodes are indicate by an underscore prefix (i.e., _:b1) and have local scope (i.e., limited to an RDF document).

Facts or statements about entities are encoded in RDF triples. An RDF triple is a 3-tuple of RDF terms, where the first element is called the *subject*, the second one the *predicate*, and the third element the *object*.

Definition 2: (RDF Triple). *An RDF triple t is defined as $t = (s, p, o)$ where $s \in \mathcal{U} \cup \mathcal{B}$ is called the subject, $p \in \mathcal{U}$ is called the predicate and $o \in \mathcal{U} \cup \mathcal{B} \cup \mathcal{L}$ is called the object.*

Informatively, the subject refers to the primary entity being described by the triple, the predicate identifies the relation between the subject and the object, which represents the value of the relation.

Example 3. The following example reports some RDF triples talking about species:

```
# PREFIX DECLARATIONS
@prefix dbr: <http://dbpedia.org/resource/>.
@prefix dbo: <http://dbpedia.org/ontology/>.
@prefix rdfs: <http://www.w3.org/2000/01/rdf-schema#>.
# RDF TRIPLES
dbr: Mouse rdfs: label "Mouse"@en.
dbr: Mouse dbo: class dbr: Mammal.
dbr: Mouse dbo: family dbr: Murinae.
dbr: Murinae rdfs: label "Murinae"@en.
dbr: Murinae dbo: family dbr: Muridae.
dbr: Murinae dbo: family dbr: Muroidea.
```

□

Here we see three prefix declarations and then six RDF triples (delimited by periods). As discussed in [Definition 2](#), each triple is composed by three RDF terms. The subject contains URIs that identify the primary resource being described (in this case, `dbr:Mouse` and `dbr:Murinae`). The predicate position contains a URI that identifies the relation being described for that resource (e.g., `rdfs:label`, `dbo:family`). The object position contains URIs and literals that refer to the value for that relation (e.g., `"Mouse"@en`, `dbr:Muroidea`).

A set of RDF triples, as those in [Example 3](#), is graphically represented as directed labeled graph, where subjects and objects are drawn as labeled vertices and predicates are drawn as directed, labeled edges. By convention, literal vertices are drawn as rectangles, and URI vertices (and blank nodes) are drawn as ellipses.

Example 4. The following picture represents the RDF triples of [Example 3](#) as a directed labeled graph.

□

It is worth nothing that since edge labels are URIs they can themselves be vertices. This happens when a predicate URI also appears in a subject or object position.

Example 5. Consider the additional following triple to the set of triples reported in [Example 3](#):

```
...
dbo:class rdfs:label "class"@en.
```

The corresponding graphical representation is the following:

A set of RDF triples is formally referred to as an RDF graph.

□

Definition 6. (RDF Graph). A set of RDF triples $G \subseteq (U \cup B) \times U \times (U \cup B \cup \mathcal{L})$ is called an RDF graph.

Since RDF graphs are defined as sets of RDF triples, it follows that the ordering of triples does not matter; moreover, duplicate triples are not allowed.

The RDF data model provides a set of predefined terms, called RDF vocabulary, having as the common prefix the core RDF namespace (rdf: <http://www.w3.org/1999/02/22-rdf-syntax-ns#>). The most widely used term in the RDF vocabulary is `rdf:type`, which encodes the fact that a given resource belongs to a particular class. Via `rdf:type` resources sharing certain commonalities are assigned to the same classes.

Example 7. Consider the following example, three instances (resources) are assigned to two different classes:

```
@prefix dbr: <http://dbpedia.org/resource/>.
@prefix dbo: <http://dbpedia.org/ontology/>.
@prefix rdfs: <http://www.w3.org/2000/01/rdf-schema#>.

dbr:Murinae rdf:type dbo:Species.
dbr:Murinae rdf:type dbo:Mammal.
dbr:Muridae rdf:type dbo:Species.
dbo:family rdf:type rdf:Property.
```

□

In general, the same resource can belong to multiple classes and each class can have multiple instances. The previous example shows in the last triple another RDF vocabulary term that is the `rdf:Property` class used to denote the set of all URIs that can appear in predicate position. For further details about the RDF standard the reader is referred to. [Consortium et al. \(2014\)](#), [Hogan \(2013\)](#).

RDF Semantics and RDF Schema

In the previous section we have covered the syntactic and structural aspects of RDF. This section describes how RDF data are *interpreted* by machines thus enabling the automation of some tasks based on the content of data.

RDF Semantics. The semantics of RDF has been defined in terms of a model-theoretic semantics ([Consortium et al., 2014](#); [Franconi et al., 2013](#)) providing a formal specification of when truth is preserved by transforming RDF data or deriving new RDF content. In particular, the RDF model theory defines RDF interpretations as possible configuration of the world and, in this setting, RDF triples are a means to make claims about the world. The more RDF triples the more specific is the world described. The interpretation provides the mathematical basis necessary to state what entities, the URIs identify in the world, what things in the world are related and by which relations (properties), what values (datatype) maps to, what entities the blank nodes refers to. The most important notion deriving from the RDF Semantics is that of *entailment*. Given an RDF graph that states a set of claims as true, the entailment helps in determining which other claims can be derived, as a consequence.

Example 8. Consider the RDF graph composed by the following RDF triples:

```
dbr:Mouse dbo:family dbr:Murinae.
dbr:Murinae dbo:family dbr:Muridae.
```

Since each RDF graph trivially entails all its subgraphs, the above RDF graph entails the following RDF graphs:

```
dbr:Mouse dbo:family dbr:Murinae.
```

and

```
dbr:Murinae dbo:family dbr:Muridae.
```

Moreover, due to the existential nature of blank nodes, it also entails the following RDF graph:

```
dbr:Mouse dbo:family dbr:Murinae.
dbr:Murinae dbo:family dbr:Muridae.
_:b1 dbo:family _:b2.
```

This last RDF graph says that there is something having some family.

□

Such form of entailment, that considers subgraphs or blank nodes, is called *simple entailment*. A more sophisticated form of entailment, called *RDF entailment*, builds upon the simple entailment.

Example 9. Consider the following RDF graph composed by the triple:

```
dbr:Mouse dbo:family dbr:Murinae.
```

This entails the following triple:

```
dbo:family rdf:type rdf:Property.
```

□

The above example shows a typical RDF entailment stating that any term appearing in the predicate position of a triple is a property, i.e., an instance of the class `rdf:Property`. The set of triples deriving from the RDF entailment can be automatically discovered by using inference rules. An inference rule has a premise, called body, and a conclusion, called head; its application generate a new conclusion (additional triples) every time the body is matched in the RDF graph.

Example 10. An inference rule to support the inference of [Example 9](#) is the following:

$?s ?p ?o \rightarrow ?p \text{ rdf:type } \text{rdf:Property}.$

□

In the above example `?s`, `?p` and `?o` are variables (variables are always prefixed with a '?'). Variables can match any RDF term in an RDF graph. In all inference rules, the variables that appear in the head must appear in the body, too. The semantics of RDF is based on the Open World Assumption (OWA), which assumes data incompleteness and all pieces of information that are not provided are unknown. In this settings, if an RDF term that appears in predicate position is not explicitly stated to be an `rdf:Property` this is not a problem. Indeed, due to the OWA, since data are incomplete a triple stating the type of such an RDF term can always be added. For further details about the RDF Semantics the interested reader is referred to [Consortium et al. \(2014\)](#), [Hogan \(2013\)](#)

RDF Schema. The RDF Schema (RDFS) specification ([Brickley et al., 2014](#)) has been proposed in 1998 to extend the RDF vocabulary. RDFS extends RDF with several key terms (see [Brickley et al. \(2014\)](#) for a complete list). The most important are the following four terms that are used to specify relationships among classes and properties: `rdfs:subClassOf` (`sc`), `rdfs:subPropertyOf` (`sp`), `rdfs:domain` (`dom`) and `rdfs:range` (`range`). `rdfs:subClassOf` is used to state that all the instances of one class are instances of another. `rdfs:subPropertyOf` is used to state that all resources related by one property are also related by another. `rdfs:domain` is used to state that any resource that is subject of a given property is an instance of one or more classes. `rdfs:range` is used to state that the objects of relations having a given property are instances of one or more classes. Among the other RDFS terms it should be mentioned the class `rdfs:Class`, which refers to the class of all classes (including itself).

The RDFS vocabulary is equipped with a model-theoretic semantics that allows to delineate RDFS entailment and define a set of RDFS inference rules. ([Consortium et al., 2014](#)). A selection of the most important (from a practical point of view) RDFS inference rules is reported in [Table 1](#); the full list is available in the RDF Semantics document 5.

Example 11. Consider the following RDF graph:

```

dbr:Mouse rdf:type dbo:Mammal.
dbr:Mus_nitidulus dbo:genus dbr:Mouse.
dbo:Mammal rdfs:subClassOf dbo:Animal.
dbo:Animal rdfs:subClassOf dbo:Eukaryote.
dbo:genus rdfs:domain dbo:Species.
dbo:Species rdfs:subClassOf owl:Thing.

```

The following triples can be RDFS-entailed from it:

```

dbo:Mammal rdfs:subClassOf dbo:Eukaryote. #rule 1 (b)
dbr:Mouse rdf:type dbo:Animal. #rule 1(a)
dbr:Mouse rdf:type dbo:Eukaryote. #rule 1(a)
dbr:Mus_nitidulus rdf:type dbo:Species. #rule 3 (a)
dbr:Mus_nitidulus rdf:type owl:Thing. #rule 3 (a)

```

Next to each inferred triple is indicated the rule from [Table 1](#) according to which it can be inferred. Note that the inference rules can also be applied to the inferred triples to infer further valid triples.

Table 1 A selection of the RDFS rule system

1. Subclass:

(a) $\frac{(?a.sc,?b) \quad (?c.type,?a)}{(?c.type,?b)} \quad (b) \quad \frac{(?a.sc,?b) \quad (?b.sc,?c)}{(?a.sc,?c)}$

2. Subproperty:

(a) $\frac{(?a.sp,?b) \quad (?c,?a,?d)}{(?c,?b,?d)} \quad (b) \quad \frac{(?a.sp,?b) \quad (?b.sp,?c)}{(?a.sp,?c)}$

3. Domain:

(a) $\frac{(?a.dom,?b) \quad (?c,?a,?d)}{(?c.type,?b)}$

4. Range:

(a) $\frac{(?a.range,?b) \quad (?c,?a,?d)}{(?d.type,?b)}$

RDFS entailment is layered on top of RDF entailment, which in turn is layered on top of simple entailment. Another form of entailment layered on top of RDF entailment and specified by the RDF Semantics document ([Consortium et al., 2014](#)) is datatype entailment or D-entailment. Such entailment has the purpose of mapping, for a set of datatypes, lexical strings to the values they denote. For example, the RDF term "25"^^xsd:decimal can be mapped to the value of the number 25.

The Web Ontology Language

The definition of Web Ontology Language (OWL) dates back to 2001 and the first version of the language was recognized as a W3C Recommendation ([McGuinness et al., 2004](#)) in 2004. Then, this first version (OWL 1) was subsequently extended by the OWL 2 W3C Recommendation ([Motik et al., 2009](#)). OWL 2 has a very similar overall structure to the first version OWL 1 and backward compatibility is kept (meaning that OWL1 ontologies are OWL 2 valid ontologies). However, OWL 2 adds new functionality with respect to OWL 1. Some of the new features are syntactic sugar (e.g., disjoint union of classes) while others offer new expressiveness (e.g., property chains and asymmetric, reflexive, and disjoint properties). OWL 2 extends RDFS with the possibility to express additional constraints and is able to represent richer and more complex knowledge about things, groups of things, and relations between things. OWL 2 is a much more intricate language than RDFS and thus, in this article we only give a high-level overview and discuss only some relevant details. Like RDFS, OWL2 statements can be expressed as RDF triples ([Grau et al., 2008](#)). Indeed, OWL 2 reuses the core RDFS vocabulary and adds some specific predicates and objects with a particular meaning. In the following a subset of the novel language constructs introduced by OWL (1/2) is summarized:

Class disjointness constraints. The predicate owl:disjointWith allows for stating that two classes are disjoint, i.e., the sets of their members have an empty intersection. As an example, the following set of RDF triples

```
:Animal rdf:type owl:Class.
:Plant rdf:type owl:Class.
:Animal owl:disjointWith:Plant.
```

states that the classes Animal and Plant cannot have any individual in common.

Class equivalence constraints: the predicate owl:equivalentClass allows for stating that two classes are equivalent, i.e., the sets of their members are the same. As an example, the following set of RDF triples

```
:Human rdf:type owl:Class.
:Person rdf:type owl:Class.
:Human owl:disjointWith dbr:Person.
```

states that the classes Human and Person are equivalent, that is very individual of type Human is also of type Person.

Property disjointness constraints: the owl:disjointPropertyWith predicate allows for stating that two properties can never interlink the same two individuals (e.g., the properties hasParent and hasSpouse cannot relate the same two people). As an example, the following set of RDF triples

```
:hasSpouse rdf:type owl:Property.
:hasParent rdf:type owl:Property.
:hasSpouse owl:disjointPropertyWith dbr:hasParent.
```

states that the properties hasSpouse and hasParent are disjoint, meaning that if an RDF document contains the triple (:a :hasSpouse :b), it cannot contain the triple (:a :hasParent :b).

Property equivalence constraints: the owl:equivalentProperty predicate allows for stating that two properties relate precisely the same individuals (e.g., the properties parentOf and hasChild are said to relate the same resources). As an example, the following set of RDF triples

```
:parentOf rdf:type owl:Property.
:hasChild rdf:type owl:Property.
:parentOf owl:equivalentProperty dbr:hasChild.
```

states that the properties parentOf and hasChild are equivalent, meaning that if an RDF documents contains the triple (:a :parentOf :b), that the triple (:a :hasChild :b) can be inferred.

Individual equivalence constraints: the predicate owl:sameAs allows for stating that two resources refer to the same individual, thus, the information for one resource applies to the other. As an example, consider the following RDF triples:

```
dbr:Mouse rdfs:label "Mouse"@en.
dbr:Mouse dbo:class dbr:Mammal.
```

```
dbr:Mouse dbo:family dbr:Murinae.
dbr:Mouse owl:sameAs wikidata:Mus.
```

The last triple establishes an `owl:sameAs` relation to another RDF resource referring to the mouse species, published by an external exporter of RDF (in this example Wikidata). On the Wikidata site, we can find, among the other, the following triples about the mouse species:

```
wikidata:Mus wikidata:taxon_name "Mus"@en.
wikidata:Mus wikidata:parent_taxon wikidata:Murinae.
```

The `owl:sameAs` link provided by DBpedia states that the two URIs refer to the same thing, in this case the mouse species. Hence, information published under one of the URIs also applies to the other URI.

Individual inequality constraints: the `owl:differentFrom` predicate allows for stating that two resources necessarily refer to different individuals; as a consequence they cannot be in an `owl:sameAs` relation and a reasoner will always deduce that they refer to distinct individuals. As an example, consider the following RDF triples:

```
dbr:Mouse rdfs:label "Mouse"@en.
dbr:Mouse dbo:class dbr:Mammal.
dbr:Mouse dbo:family dbr:Murinae.
dbr:Mouse owl:differentFrom dbr:Yeast.
```

The `owl:differentFrom` link states that the two URIs refer to different things.

Property inverse constraints: the predicate `owl:inverseOf` allows for stating that one property relates the same things as another property, but in the opposite direction; that is, If the property P1 is stated to be the inverse of the property P2, then if X is related to Y by the P2 property, then Y is related to X by the P1 property. As an example, consider the following RDF triples:

```
:a :hasChild :b.
:hasChild owl:inverseOf :hasParent.
```

The `owl:inverseOf` link states that `:hasChild` is the inverse of `hasParent`. Thus, it is possible to infer the additional triple (`:b :hasParent :a`).

Property transitive constraints: the `owl:TransitiveProperty` predicate is used to state that a property is transitive; that is, if the pair (a,b) is an instance of a transitive property P, and the pair (b,c) is an instance of P, then the pair (a,c) is also an instance of P. As an example, consider the following RDF triples:

```
:a :ancestorOf :b.
:b :ancestorOf :c.
:ancestorOf rdf:type owl:TransitiveProperty.
```

The last triple states that `:ancestorOf` is a transitive property. Thus, it is possible to infer the additional triple (`:a:ancestorOf:c`).

Property symmetric constraints: the `owl:SymmetricProperty` predicate is used to state that a property is symmetric; that is, if the pair (a,b) is an instance of the symmetric property P, then the pair (b,a) is also an instance of P. As an example, consider the following RDF triples:

```
:a :friend :b.
:friend rdf:type owl:SymmetricProperty.
```

The last triple states that `:friend` is a symmetric property. Thus, it is possible to infer the additional triple (`:b :friend :a`).

Property functional constraints: the `owl:FunctionalProperty` predicate allows to state that a subject resource can have at most one value for such property; that is, `FunctionalProperty` is shorthand for stating that the property's minimum cardinality is zero and its maximum cardinality is 1. As an example, consider the following RDF triples:

```
:a :hasBiologicalFather :b.
:a :hasBiologicalFather :c.
:hasBiologicalFather rdf:type owl:FunctionalProperty.
```

The last triple states that `:hasBiologicalFather` is a functional property. Thus, it is possible to infer the additional triple (`:b owl:sameAs :c`).

Inverse functional constraints of properties: this type of constrain, expressed via the predicate `owl:InverseFunctionalProperty`, allows for stating that the inverse of a property is functional, meaning that the value of a property is unique to the subject of the relation

(e.g., ISBN values uniquely identify books). If two subjects share the same object for a given inverse-functional property it means that they refer to the same individual. As an example, consider the following RDF triples:

```
:b :isBiologicalFather :a.  
:c :isBiologicalFather :a.  
:isBiologicalFather rdfs:type owl:InverseFunctionalProperty.
```

The last triple states that `:isBiologicalFather` is an inverse functional property. Thus, it is possible to infer the additional triple (`:b owl:sameAs :c`).

Intentional class definition: A main feature of OWL is the intentional definition of new classes from existing ones; the keyword `owl:Restriction` is used for defining a new class by using some specific restriction properties.

Property and Cardinality restrictions: Allows to express restrictions on how properties can be used by the instances of a class and are used within the context of an `owl:Restriction`.

- The predicate `owl:someValuesFrom` allows to state that at least one value of the property `P` comes from a given class `C`. As an example, consider the following RDF triples:

```
_:a rdfs:subClassOf owl:Restriction.  
_:a owl:onProperty :leads.  
_:a owl:someValuesFrom :Scientist.  
:Department rdfs:subClassOf :a.
```

The above triples constraint that every department must be led at least by one scientist.

- The predicate `owl:allValuesFrom` enables to restrict the range of a property for a given class. This means that for all individuals of such a class the value of such property must be an individual respecting the range restriction criteria. As an example, consider the following RDF triples:

```
_:a rdfs:subClassOf owl:Restriction.  
_:a owl:onProperty :leads.  
_:a owl:allValuesFrom :Scientist.  
:Department rdfs:subClassOf :a.
```

The above triples constraint that every department can be led only by scientists.

- The predicates `owl:minCardinality` and `owl:maxCardinality` allow to indicate the minimum number and maximum number of relations of a given type that all individuals of a given class must have, respectively. As an example, consider the following RDF triples:

```
_:a rdfs:subClassOf owl:Restriction  
_:a owl:onProperty :leads  
_:a owl:minCardinality 3  
_:b rdfs:subClassOf owl:Restriction  
_:b owl:onProperty :leads  
_:b owl:maxCardinality 6  
:Department rdfs:subClassOf :a.  
:Department rdfs:subClassOf :b.
```

The above triples constraint that every department can have at least 3 and at most six leaders.

- The predicate `owl:cardinality` allows to indicate the exact number of relations of a given type that all individuals of a given class must have. As an example, consider the following RDF triples:

```
_:a rdfs:subClassOf owl:Restriction  
_:a owl:onProperty :leads  
_:a owl:cardinality 3  
:Department rdfs:subClassOf :a.
```

The above triples constraint that every department must have exactly 3 leaders.

Set operations over classes: OWL contains some set-based constructors that allow to combine classes.

- The constructor `owl:intersectionOf` enables to specify the intersection of classes; the intersection of classes denotes the individuals that belong to both classes. As an example, consider the following RDF triples:

```
_:a rdfs:subClassOf owl:Restriction
_:a owl:onProperty :teachesTo
_:a owl:someValuesFrom :Graduated
_:b owl:intersectionOf (:Professor, :Lecturer)
_:a rdfs:subClassOf _:b
```

The above triples constraint that only professors and lecturers may teach to graduate students.

- The constructor `owl:unionOf` allows to specify the union of classes; the union of classes denotes the individuals that belong to some classes. As an example, consider the following RDF triples:

```
_:a rdfs:subClassOf owl:Restriction
_:a owl:onProperty :teachesTo
_:a owl:someValuesFrom :Undergraduated
_:b owl:unionOf (:Professor, :Lecturer)
_:a rdfs:subClassOf _:b
```

The above triples constraint that both professors and lecturers may teach to undergraduate students.

- The constructor `owl:complementOf` enables to specify the complement of a class; the complement of a class denotes the individuals that do not belong to the class. As an example, consider the following RDF triples:

```
_:a rdfs:subClassOf owl:Restriction
_:a owl:onProperty :teachesTo
_:a owl:someValuesFrom :Undergraduated
_:b owl:complement (:Professor)
_:a rdfs:subClassOf _:b
```

The above triples constraint that professors cannot teach to undergraduate students.

In **Table 2** some of the inference rules that correspond to such OWL features (and are a subset of the complete list of the OWL 2 RL/RDF rules ([Motik et al., 2009](#))) are reported. In the table, the head of the rule FALSE indicates that data are inconsistent.

Now, we give an example of how the above inference rules are applied. Consider the following two RDF graphs:

```
dbr:Mouse rdfs:label "Mouse"@en.
dbr:Mouse dbo:class dbr:Mammal.
dbr:Mouse dbo:family dbr:Murinae.
dbr:Mouse owl:sameAs wikidata:Mus.
```

and

```
wikidata:Mus wikidata:taxon_name "Mus"@en.
wikidata:Mus wikidata:parent_taxon wikidata:Murinae.
```

The `owl:sameAs` link provided in the first graph states that the two URIs `dbr:Mouse` and `wikidata:Mus` refer to the same thing. Hence, information published about `dbr:Mouse` or about `wikidata:Mus` also applies to the other URI. This feature of OWL is axiomatized by rules `eq-trans`, `eq-rep-s`, `eq-rep-p` and `eq-rep-o` in the above Table. Applying these rules, one can see that the above two graphs entail:

```
dbr:Mouse wikidata:taxon_name "Mus"@en.
dbr:Mouse wikidata:parent_taxon wikidata:Murinae.
wikidata:Mus owl:sameAs dbr:Mouse.
wikidata:Mus rdfs:label "Mouse"@en.
wikidata:Mus dbo:class dbr:Mammal.
wikidata:Mus dbo:family dbr:Murinae.
wikidata:Mus owl:sameAs wikidata:Mus.
```

Among the typical reasoning tasks that can be performed over an OWL ontology there are consistency checking (checking if the data lead to some inconsistency), satisfiability checking (checking if a class can have a member without causing a logical contradiction), subsumption checking (checking if a class is necessarily a sub-class of another), instance checking (checking if a resource is a member of a class) and conjunctive query answering (posing complex queries against the ontology and its entailments). To solve this

Table 2 A subset of OWL inference rules

Name	Rule
eq-sym	$?x \text{ owl:sameAs } ?y. \rightarrow ?y \text{ owl:sameAs } ?x.$
eq-trans	$?x \text{ owl:sameAs } ?y. ?y \text{ owl:sameAs } ?z. \rightarrow ?x \text{ owl:sameAs } ?z.$
eq-rep-s	$?s \text{ owl:sameAs } ?x. ?s ?p ?o. \rightarrow ?x ?p ?o.$

reasoning tasks OWL defines two standard and compatible semantics. The first semantics is called the “RDF-Based Semantics”, and it is backwards-compatible with RDF. However, all the above reasoning tasks are undecidable. This means that it cannot be guaranteed that the automated reasoning process ever terminates. The second semantics, called the Direct Semantics, can only interpret OWL ontologies satisfying certain restrictions. These restrictions are such that certain reasoning tasks are known to be decidable. This introduces a trade of some expressive power of the language (features it supports) for the efficiency of reasoning. OWL 2 define three profiles (Motik *et al.*, 2009) that achieve efficiency in a different way and are useful in different application scenarios.

OWL 2 EL. This was the first OWL profile to be defined and is particularly useful in applications employing ontologies that contain very large numbers of properties and/or classes. The basic reasoning problems for this profile can be performed in time that is polynomial with respect to the size of the ontology. As an example, OWL 2 EL, among the others, does not allow to use inverse or symmetric properties.

OWL 2 QL. This was the second OWL profile and is aimed at applications that use very large volumes of instance data where query answering is the most important reasoning task. Query answering is solved by rewriting queries over relational database systems.

OWL 2 RL. This is the third OWL profile and is aimed at applications that require scalable reasoning without sacrificing too much expressive power. The ontology consistency, class expression satisfiability, class expression, subsumption, instance checking, and conjunctive query answering problems can be solved in time that is polynomial with respect to the size of the ontology.

Concluding Remarks

Ontologies are a key ingredient toward modeling and reasoning over knowledge domains. In this article we gave an overview of the ontology language defined under the W3C (the World Wide Web Consortium) umbrella. We have started from RDF, a simple language to express statements, and reached OWL, which offers very sophisticated reasoning capabilities. Instead of focusing on too much technicalities and formalism, our treatment gave special attention to concrete examples. This approach will hopefully allow to better grasp the core ideas beyond these ontology languages thus making them useful in concrete application scenarios.

Ontology: Querying Languages and Development

Introduction

The use of ontologies as a support to model knowledge domains and enable a new form of knowledge-based services has significantly increased in the last decade. Ontologies represent an underlying knowledge support for modeling domains (Gruber *et al.*, 1993), and thus is of utmost importance the definition of ontology-building methodologies (Fernández-López *et al.*, 1997). Ontologies have played a key role in a variety of tasks from knowledge management/retrieval (e.g., ontology based data access (Calvanese *et al.*, 2011)) to distributed systems (e.g., ontology-based query routing (Pirrò *et al.*, 2009) or resource finding (Atencia *et al.*, 2011)). A very prominent example of the importance of ontologies derives from the Semantic Web project (Berners-Lee *et al.*, 2001).

In this context new problems related to the creation and management of ontologies raised along with new opportunities to use ontologies in a variety of tasks including querying and reasoning. A significant contribution to the spread of ontologies has been given by standardization bodies such as the World Wide Web Consortium (W3C) (see Relevant Website section). Nowadays, ontologies languages like RDF, RDFS (Franconi *et al.*, 2013), and OWL have now reached a significant level of maturity that make them suitable for the usage in different practical contexts. To support the ontology management a plethora of tools has been defined (Perez *et al.*, 2002). Retrieval and reasoning are among the most two important functionalities enabled by ontologies.

Focusing on these two aspects, in this article, we first discuss the SPARQL language (Section SPARQL), a W3C standard for querying RDF data and then illustrate how it can also be used to query an ontology. Then, we provide (Section Ontology Management Tools) a high level overview of about some popular ontology management tools. We conclude in Section Concluding Remarks.

SPARQL

The SPARQL standard defines a query language proposed specifically for RDF data. The first proposal for the SPARQL specification became a W3C Recommendation in 2008 (Prud'hommeaux and Seaborne, 2008). Then, in 2013, an extension of the standard, called SPARQL 1.1, became a W3C Recommendation (Harris *et al.*, 2013). The SPARQL language is orthogonal to RDFS and OWL; indeed, it is built directly on top of the RDF data model and does not provide direct support for inferencing. Before introducing SPARQL we introduce the following notation; I is the set of all URIs, L be the set of all literals and $\mathcal{V}$ be a countably infinite set of variables, such that $\mathcal{V} \cap (I \cup L) = \emptyset$. Variables in SPARQL are string preceded by the ? symbol.

SPARQL is similar in spirit and structure to the Structured Query Language (SQL) used for querying relational databases, but designed to work specifically on RDF data. In what follows we will discuss both the syntax and semantics of SPARQL queries. The SPARQL semantics is formalized along the lines of Angles and Gutierrez (Angles and Gutierrez, 2016).

By analyzing SPARQL queries on a high level of details, we can identify five main parts: (i) **Prefix Declarations** that allow for defining URI prefixes that can be used as shortcuts in a SPARQL query; (ii) **Dataset Clause** that allows for specifying the dataset over which the query is to be executed; (iii) **Result Clause** that allows to specify the type of SPARQL query and what results should be returned; (iv) **Query Clause** that allows to specify the query patterns; (v) **Solution Modifiers** that allows to express some ordering and partitioning of the results.

Example 1. Consider the SPARQL query reported below. Comments lines are prefixed with a sharp ('#'). The first block defines the prefixes that can be used later in the query. The second block (Dataset Clause) specifies the dataset on which the query should be executed: in this case an RDF document on the DBpedia site about the mouse species. The third block (the Result Clause) allows to define which kind of results should be returned (in this case the keyword *DISTINCT* forces the result pairs matching the variables *?class* and *?family* to be unique). The fourth block (Query Clause) defines the patterns that the query should match against the data. In this example we are looking for the values of the *dbo: class* and *dbo: family* of *dbr: Mouse*. The last block (Solution Modifiers) is used to set a limit on the number of results returned via the keyword *LIMIT*.

```
# PREFIX DECLARATIONS
PREFIX dbr: <http://dbpedia.org/resource/>
PREFIX dbo: <http://dbpedia.org/ontology/>

# DATASET CLAUSE
FROM <http://dbpedia.org/data/Mouse.xml>

# RESULT CLAUSE
SELECT DISTINCT ?class ?family
```

```
# QUERY CLAUSE
WHERE {
  dbr:Mouse dbo:class ?class.
  dbr:Mouse dbo:family ?family.
}
```

```
# SOLUTION MODIFIER
LIMIT 2
```

Assuming the existence of the following triples:

```
dbr : Mouse dbo : class dbr : Mammal.
dbr : Mouse dbo : family dbr : Murinae.
dbr : Mouse dbo : family dbr : Muridae.
dbr : Mouse dbo : family dbr : Muroidea.
```

in the RDF graph `<http://dbpedia.org/data/Mouse.xml>`, a result for the above query is the binding of the variables `?class` and `?family` as follows:

<code>?class</code>	<code>?family</code>
dbr : Mouse	dbr : Murinae
dbr : Mouse	dbr : Muridae

where the header indicates the variables for which the respective terms are bound in the results. □

In what follows the Dataset Clause, Result Clause, Query Clause and Solution Modifiers are detailed.

Query Types

A SPARQL query can be one of the following four types:

SELECT [DISTINCT]: the result is a list of bindings for variables specified in the query. By default the result can contain duplicate bindings; the use of the keyword **DISTINCT** has the effect of eliminating duplicates.

ASK: the result is a boolean value indicating whether or not there was a match in the data for the specified query.

CONSTRUCT: the result is an RDF graph (instead of a (multi)set of bindings). An RDF template is provided where variable bindings can be inserted.

DESCRIBE: the result is the RDF description of a particular RDF term. Common types of descriptions are all the triples in which the RDF term appears at (i) any position, (ii) as a subject, or (iii) as a subject or object.

Dataset Clause and Named Graphs

In general, a SPARQL dataset is composed by several RDF graphs.

Definition 2. A SPARQL named graph is a pair (u, G) where $u \in I$ is a URI representing the name of the RDF graph G .

A SPARQL dataset is then composed of a default graph, which has no name, and a set of named graphs.

Definition 3. A SPARQL dataset $D = \{G, (u_1, G_1), \dots, (u_n, G_n)\}$ is a set of RDF graphs where $u_1, \dots, u_n$ are distinct URIs and $G, G_1, \dots, G_n$ are RDF graphs. The unnamed graph G is the default graph. Each pair (u_i, G_i) is a named graph.

Since a SPARQL dataset is composed by several graphs, it is possible to query different partitions of it, by using the names of the individual graphs. The selection of the partition to use is done in the dataset clause of the query, by using one of the two following optional features:

- **FROM:** this keyword is used to specify the default graph;
- **FROM NAMED:** this keyword is used to specify a set of named graphs via their URIs.

Query patterns in the query clause are matched against the default graph. If another graph should be used it must be explicitly declared by using in the query clause the keyword **GRAPH**. For queries that do not contain any dataset clause, usually SPARQL query engines use as a default graph the union of all the RDF graphs in the dataset.

Query Clause

The query clause specifies the SPARQL graph patterns that query variables must match. It starts with the keyword **WHERE** and is surrounded by curly brackets.

Definition 4. A SPARQL graph pattern is defined recursively as follows:

- A triple from $(I \cup L \cup V) \times (I \cup V) \times (I \cup L \cup V)$ is a graph pattern called a triple pattern. (We do not consider blank nodes since in RDF triple patterns they are handled as existential variables.).
- If $\mathcal{P}_1$ and $\mathcal{P}_2$ are graph patterns then $(\mathcal{P}_1 \text{ AND } \mathcal{P}_2)$, $(\mathcal{P}_1 \text{ UNION } \mathcal{P}_2)$, $(\mathcal{P}_1 \text{ OPTIONAL } \mathcal{P}_2)$, $(\mathcal{P}_1 \text{ MINUS } \mathcal{P}_2)$ and $(\mathcal{P}_1 \text{ NOT-EXISTS } \mathcal{P}_2)$ are graph patterns.
- If $\mathcal{P}_1$ is a graph pattern and C is a filter constraint (as defined below) then $(\mathcal{P}_1 \text{ FILTER } C)$ is a graph pattern.

Triple patterns and basic graph patterns

Triple patterns can be executed against RDF graphs to produce a (multi)set of solution mappings. Given a triple pattern t we next indicate with $\text{var}(t)$ the set of variables that appear in t .

Definition 5. A (solution) mapping μ is a partial function $\mu : V \rightarrow I \cup L$, where $\text{dom}(\mu)$ indicates the set of variables over which the mapping is defined.

Each mapping applied to the triple pattern returns a triple belonging to the RDF graph. Given a triple pattern t and a mapping μ such that $\text{var}(t) \subseteq \text{dom}(\mu)$, we denote by $\mu(t)$ the triple obtained by replacing the variables in t according to μ . Overloading the above definition, we denote by $\mu(\mathcal{P})$ the graph pattern obtained by the recursive substitution of variables in every triple pattern and filter constraint occurring in the graph pattern $\mathcal{P}$ according to μ . The *empty mapping*, denoted μ_0 , is the mapping satisfying that $\text{dom}(\mu_0) = \emptyset$.

A set of triple patterns is called basic graph pattern (BGP). An example of BGP is reported in Example 1, where two triple patterns (i.e., `dbr:Mouse dbo:class ?class` and `dbr:Mouse dbo:family ?family`) are embedded in the WHERE clause. The set of triple patterns included in a basic graph pattern are considered as a conjunction. This conjunction leads to a join operation over compatible mappings belonging to the sets of mappings produced by evaluating individual triple patterns.

Definition 6. Two mappings μ_1 and μ_2 are compatible (resp., not compatible), denoted by $\mu_1 \sim \mu_2$ (resp., $\mu_1 \not\sim \mu_2$), if $\mu_1(?X) = \mu_2(?X)$ for all variables $?X \in (\text{dom}(\mu_1) \cap \text{dom}(\mu_2))$ (resp., if $\mu_1(?X) \neq \mu_2(?X)$ for some $?X \in (\text{dom}(\mu_1) \cap \text{dom}(\mu_2))$).

If $\mu_1 \sim \mu_2$ then we write $\mu_1 \cup \mu_2$ for the mapping obtained by extending μ_1 according to μ_2 on all variables in $\text{dom}(\mu_2) \setminus \text{dom}(\mu_1)$. Note that two mappings with disjoint domains are always compatible, and that the empty mapping μ_0 is compatible with any other mapping.

Given a finite set of variables $W \subseteq V$, the restriction of a mapping μ to W , denoted $\mu|_W$, is a mapping μ' satisfying that $\text{dom}(\mu') = \text{dom}(\mu) \cap W$ and $\mu'(?X) = \mu(?X)$ for every $?X \in \text{dom}(\mu) \cap W$.

Filter constraints

A filter constraint is defined recursively as follows:

1. If $?X, ?Y \in V$ and $c \in I \cup L$ then $(?X=c)$, $(?X=?Y)$ and $\text{bound} (?X)$ are *atomic filter constraints*;
2. If C_1 and C_2 are filter constraints then $(!C_1)$, $(C_1 \parallel C_2)$ and $(C_1 \&\& C_2)$ are *complex filter constraints*.

Given a filter constraint C , we denote by $f(C)$ the selection formula obtained from C . A *selection formula* is defined recursively as follows: (i) If $?X, ?Y \in V$ and $c \in I \cup L$ then $(?X=c)$, $(?X=?Y)$ and $\text{bound} (?X)$ are atomic selection formulas; (ii) If F and F' are selection formulas then $(F \wedge F')$, $(F \vee F')$ and $\neg(F)$ are boolean selection formulas. The evaluation of a selection formula F under a mapping μ , denoted $\mu(F)$, is defined in a three-valued logic (i.e. with values *true*, *false*, and *error*) as follows:

- If F is $?X=c$ and $?X \in \text{dom}(\mu)$, then $\mu(F) = \text{true}$ when $\mu(?X) = c$ and $\mu(F) = \text{false}$ otherwise. If $?X \notin \text{dom}(\mu)$ then $\mu(F) = \text{error}$.
- If F is $?X=?Y$ and $?X, ?Y \in \text{dom}(\mu)$, then $\mu(F) = \text{true}$ when $\mu(?X) = \mu(?Y)$ and $\mu(F) = \text{false}$ otherwise. If either $?X \notin \text{dom}(\mu)$ or $?Y \notin \text{dom}(\mu)$ then $\mu(F) = \text{error}$.
- If F is $\text{bound} (?X)$ and $?X \in \text{dom}(\mu)$ then $\mu(F) = \text{true}$ else $\mu(F) = \text{false}$.
- If F is a complex selection formula then it is evaluated following the three-valued logic presented in [Table 1](#).

Note that there exists a simple and direct translation from filter constraints to selection formulas and viceversa.

Combining graph patterns

On top of Basic Graph Patterns and Filter constraints, SPARQL defines six other core features that can be used to create complex query patterns in query clauses:

- **GRAPH:** If used in conjunction with a URI, this keyword specifies a named graph against which a graph pattern should be matched. If used in conjunction with a variable, such a variable is used to bind the named graph for which the graph pattern is matched.
- **AND:** (In the SPARQL syntax the keyword AND is omitted.) Allows the definition of a conjunction of graph patterns that the query should match. The result is the join of the solution mappings generated for each conjunctive query pattern.
- **UNION:** Allows the definition of a disjunction of graph patterns that the query should match. The result is the union of the solution mappings generated for each disjunctive query pattern.

Table 1 Three-valued logic for evaluating selection formulas

p	q	$p \wedge q$	$p \vee q$		
true	true	true	true		
true	false	false	true		
true	error	error	true		
false	true	false	true	p	$\neg p$
false	false	false	false	true	false
false	error	false	error	false	true
error	true	error	true	error	error
error	false	false	error		
error	error	error	error		

- **OPTIONAL**: It is used to specify optional graph patterns. If an optional graph pattern cannot be matched the variables that are unique in the optional pattern are mapped to UNBOUND (a SPARQL keyword denoting the fact that a variable is not bound).
- **MINUS**: it is used to specify negation. This operator evaluates both its arguments, then calculates solutions in the left-hand side that are not compatible with any solution on the right-hand side.
- **NOT EXISTS**: it is another type of negation that filter expression tests whether a graph pattern does not match the dataset, given the values of variables in the graph pattern in which the filter occurs.

Property paths

Property paths (PPs) have been incorporated into the SPARQL 1.1 standard with two main motivations; first, to provide explicit graph navigational capabilities thus allowing the writing of SPARQL navigational queries in a more succinct way; second, to introduce transitive closure $*$ previously not available in SPARQL. The design of PPs was influenced by earlier proposals (e.g., nSPARQL (Pérez et al., 2010)) and inspired several extensions (e.g., Extended Property Paths (Fionda et al., 2015), Property Paths over the Web (Hartig and Pirrò, 2015), and languages for the Web (Fionda et al., 2015)).

Definition 7. A property path pattern (or PP pattern for short) is a tuple $\mathcal{P} = \langle \alpha, \text{elt}, \beta \rangle$ with $\alpha \in (I \cup L \cup \mathcal{V})$, $\beta \in (I \cup L \cup \mathcal{V})$, and elt is a property path expression (PP expression) that is defined by the following grammar (where $u, u_1, \dots, u_n \in I$):

$$\text{elt} := u | (u_1 | \dots | u_n) | !(\wedge u_1 | \dots | \wedge u_n) | !(\wedge u_1 | \dots | \wedge u_j | \dots | \wedge u_q | \dots | \wedge u_n) | \text{elt} / \text{elt} | (\text{elt} | \text{elt}) | (\text{elt})^* | \wedge \text{elt}$$

The SPARQL standard introduces additional types of PP expressions (Harris et al., 2013); since these are merely syntactic sugar (they are defined in terms of expressions covered by the grammar given above), we ignore them in this article. As another slight deviation from the standard, we do not consider blank nodes in PP patterns. PP patterns with blank nodes can be simulated using fresh variables. The SPARQL standard distinguishes between two types of property path expressions: *connectivity patterns* or recursive PPs that include closure ($*$), and *syntactic short forms* or non-recursive PPs (nPPs) that do not include it. As for the evaluation of PPs, the W3C spec. informally mentions the fact that nPPs can be evaluated via a translation into equivalent SPARQL basic expressions (see Harris et al., 2013, Section 9.3). Property path patterns can be combined with graph patterns inside SPARQL patterns (using PP expressions in the middle position of a pattern).

SPARQL semantics

The evaluation of a SPARQL graph pattern $\mathcal{P}$ over an RDF graph G is defined as a function $\llbracket \mathcal{P} \rrbracket_G$ which returns a multiset of solution mappings. We use the symbol Ω to denote a multiset and $\text{card}(\mu, \Omega)$ to denote the cardinality of the mapping μ in the multiset Ω . Moreover, it applies that $\text{card}(\mu, \Omega) = 0$ when $\mu \notin \Omega$. We use Ω_0 to denote the multiset $\{\mu_0\}$ such that $\text{card}(\mu_0, \Omega_0) > 0$ (Ω_0 is called the join identity). The domain of a solution mapping Ω is defined as $\text{dom}(\Omega) = \cup_{\mu \in \Omega} \text{dom}(\mu)$. The SPARQL algebra for multisets of mappings is composed of the operations of projection, selection, join, difference, left-join, union and minus. Let Ω_1, Ω_2 be multisets of mappings, W be a set of variables and F be a selection formula.

Definition 8. (Operations over multisets of mappings). Let Ω_1 and Ω_2 be multiset of mappings, then:

- Projection:** $\pi_W(\Omega_1) = \{\mu' | \mu \in \Omega_1, \mu' = \mu|_W\}$ where $\text{card}(\mu', \pi_W(\Omega_1)) = \sum_{\mu' = \mu|_W} \text{card}(\mu, \Omega_1)$.
- Selection:** $\sigma_F(\Omega_1) = \{\mu \in \Omega_1 | \mu(F) = \text{true}\}$ where $\text{card}(\mu, \sigma_F(\Omega_1)) = \text{card}(\mu, \Omega_1)$.
- Union:** $\Omega_1 \cup \Omega_2 = \{\mu | \mu \in \Omega_1 \vee \mu \in \Omega_2\}$ where $\text{card}(\mu, \Omega_1 \cup \Omega_2) = \text{card}(\mu, \Omega_1) + \text{card}(\mu, \Omega_2)$.
- Join:** $\Omega_1 \bowtie \Omega_2 = \{\mu = (\mu_1 \cup \mu_2) | \mu_1 \in \Omega_1, \mu_2 \in \Omega_2, \mu_1 \sim \mu_2\}$, $\text{card}(\mu, \Omega_1 \bowtie \Omega_2) = \sum_{\mu = (\mu_1 \cup \mu_2)} \text{card}(\mu_1, \Omega_1) \times \text{card}(\mu_2, \Omega_2)$.
- Difference:** $\Omega_1 \setminus_F \Omega_2 = \{\mu_1 \in \Omega_1 | \forall \mu_2 \in \Omega_2, (\mu_1 \sim \mu_2) \vee (\mu_1 \sim \mu_2 \wedge (\mu_1 \cup \mu_2)(F) = \text{false})\}$ where $\text{card}(\mu_1, \Omega_1 \setminus_F \Omega_2) = \text{card}(\mu_1, \Omega_1)$.
- Minus:** $\Omega_1 - \Omega_2 = \{\mu_1 \in \Omega_1 | \forall \mu_2 \in \Omega_2, \mu_1 \sim \mu_2 \vee \text{dom}(\mu_1) \cap \text{dom}(\mu_2) = \emptyset\}$ where $\text{card}(\mu_1, \Omega_1 - \Omega_2) = \text{card}(\mu_1, \Omega_1)$.
- Left Join:** $\Omega_1 \bowtie_L \Omega_2 = \sigma_F(\Omega_1 \bowtie \Omega_2) \cup (\Omega_1 \setminus_F \Omega_2)$ where $\text{card}(\mu, \Omega_1 \bowtie_L \Omega_2) = \text{card}(\mu, \sigma_F(\Omega_1 \bowtie \Omega_2)) + \text{card}(\mu, \Omega_1 \setminus_F \Omega_2)$.

Let $\mathcal{P}_1, \mathcal{P}_2, \mathcal{P}_3$ be graph patterns and C be a filter constraint. The evaluation of a graph pattern $\mathcal{P}$ over a graph G is defined recursively as follows:

- If $\mathcal{P}$ is a triple pattern t_p then $\llbracket t_p \rrbracket_G = \{\mu \mid \text{dom}(\mu) = \text{var}(t_p) \text{ and } \mu(t_p) \in G\}$ where $\text{var}(t_p)$ is the set of variables in t_p and the cardinality of each mapping is 1.
- If $\mathcal{P} = (\mathcal{P}_1 \text{ AND } \mathcal{P}_2)$, then $\llbracket \mathcal{P} \rrbracket_G = \llbracket \mathcal{P}_1 \rrbracket_G \bowtie \llbracket \mathcal{P}_2 \rrbracket_G$
- If $\mathcal{P} = (\mathcal{P}_1 \text{ UNION } \mathcal{P}_2)$, then $\llbracket \mathcal{P} \rrbracket_G = \llbracket \mathcal{P}_1 \rrbracket_G \sqcup \llbracket \mathcal{P}_2 \rrbracket_G$
- If $\mathcal{P} = (\mathcal{P}_1 \text{ OPTIONAL } \mathcal{P}_2)$, then: then
 - (a) if $\mathcal{P}_2$ is $(\mathcal{P}_3 \text{ FILTER } C)$ then $\llbracket \mathcal{P} \rrbracket_G = \llbracket \mathcal{P}_1 \rrbracket_G \bowtie_{f(C)} \llbracket \mathcal{P}_3 \rrbracket_G$
 - (b) else $\llbracket \mathcal{P} \rrbracket_G = \llbracket \mathcal{P}_1 \rrbracket_G \bowtie_{(true)} \llbracket \mathcal{P}_3 \rrbracket_G$
- If $\mathcal{P} = (\mathcal{P}_1 \text{ MINUS } \mathcal{P}_2)$, then $\llbracket \mathcal{P} \rrbracket_G = \llbracket \mathcal{P}_1 \rrbracket_G - \llbracket \mathcal{P}_2 \rrbracket_G$
- If $\mathcal{P} = (\mathcal{P}_1 \text{ NOT- EXISTS } \mathcal{P}_2)$, then $\llbracket (\mathcal{P}_1 \text{ NOT- EXISTS } \mathcal{P}_2) \rrbracket_G = \{\mu \mid \mu \in \llbracket \mathcal{P}_1 \rrbracket_G \wedge \llbracket \mu(\mathcal{P}_2) \rrbracket_G = \emptyset\}$
- If $\mathcal{P} = (\mathcal{P}_1 \text{ FILTER } C)$, then $\llbracket \mathcal{P}_1 \text{ FILTER } C \rrbracket_G = \sigma_{f(C)}(\llbracket \mathcal{P}_1 \rrbracket_G)$

The semantics of PPs is shown in [Fig. 1](#). The semantics uses the evaluation function $\llbracket \langle a, elt, b \rangle \rrbracket_G$, which takes as input a PP pattern and a graph and returns a multiset of solution mappings. In [Fig. 1](#) we do not report all the combinations of types of patterns as they can be derived in a similar way. For connectivity patterns the SPARQL standard introduces auxiliary functions called ALP, which stands for Arbitrary Length Paths (see [Fig. 2](#)); in this case the evaluation does not admit duplicates thus solving a problem in an early version of the semantics that was based on counting and lead to intractability ([Arenas et al., 2012](#)).

The solution mappings from the query clause, that is the solution mappings obtained by evaluating the query pattern contained in query clause, can be further chopped and changed through the solution modifiers discussed in Section Solution Modifiers.

Solution Modifiers

Solution modifiers can be used to post-process results produced from the query clause. SPARQL offers the following solution modifiers:

- ORDER BY [ASC | DESC]: it allows to sort results. Sorting is performed lexicographically based on variable order. The optional ASC and DESC keywords allow to specify whether for specific variables the sorting should be ascending or descending.
- LIMIT: it allows to indicate a non-negative integer n that specifies the maximum number of results to return.
- OFFSET: it allows to specify a non-negative integer indicating how many results should be skipped. In combination with LIMIT, this allows for a form of pagination of results. However, since no default order can be assumed in the results, OFFSET is only useful in combination with ORDER BY.

Using SPARQL to Query Ontologies

The SPARQL language is orthogonal to the RDFS and OWL, indeed, it is built directly on top of the RDF data-model and does not provide direct support for inferencing. However, being a query language proposed for RDF data, SPARQL can be used to query

$$\begin{aligned}
 \llbracket \langle \alpha, u, \beta \rangle \rrbracket_G &:= \{ \mu \mid \text{dom}(\mu) = (\{\alpha, \beta\} \cap \mathcal{V}) \text{ and } \mu(\langle \alpha, u, \beta \rangle) \in G \}, \text{card}(\mu, \Omega) = 1 \\
 \llbracket \langle \alpha, !(u_1 \mid \dots \mid u_n), \beta \rangle \rrbracket_G &:= \{ \mu \mid \text{dom}(\mu) = (\{\alpha, \beta\} \cap \mathcal{V}), \exists u \in \mathbf{I} \text{ such that } u \notin \{u_1, \dots, u_n\} \text{ and} \\
 &\quad \mu(\langle \alpha, u, \beta \rangle) \in G \} \text{ and } \text{card}(\mu, \Omega) = |\{u \mid u \in \mathbf{I}, u \notin \{u_1, \dots, u_n\}, \\
 &\quad \mu(\langle \alpha, u, \beta \rangle) \in G \}| \\
 \llbracket \langle \alpha, \hat{elt}, \beta \rangle \rrbracket_G &:= \llbracket \langle \beta, elt, \alpha \rangle \rrbracket_G \\
 \llbracket \langle \alpha, elt_1 / elt_2, \beta \rangle \rrbracket_G &:= \pi_{\{\alpha, \beta\} \cap \mathcal{V}} \left(\llbracket \langle \alpha, elt_1, ?v \rangle \rrbracket_G \bowtie \llbracket \langle ?v, elt_2, \beta \rangle \rrbracket_G \right) \\
 \llbracket \langle \alpha, (elt_1 \mid elt_2), \beta \rangle \rrbracket_G &:= \llbracket \langle \alpha, elt_1, \beta \rangle \rrbracket_G \sqcup \llbracket \langle \alpha, elt_2, \beta \rangle \rrbracket_G \\
 \llbracket \langle x_L, (elt)^*, ?v_R \rangle \rrbracket_G &:= \{ \mu \mid \text{dom}(\mu) = \{?v_R\} \text{ and } \mu(?v_R) \in \text{ALP1}(x_L, elt, G) \}, \text{card}(\mu, \Omega) = 1 \\
 \llbracket \langle ?v_L, (elt)^*, ?v_R \rangle \rrbracket_G &:= \{ \mu \mid \text{dom}(\mu) = \{?v_L, ?v_R\} \text{ and } \mu(?v_L) \in \text{terms}(G) \text{ and} \\
 &\quad \mu(?v_R) \in \text{ALP1}(\mu(?v_L), elt, G) \}, \text{card}(\mu, \Omega) = 1 \\
 \llbracket \langle ?v_L, (elt)^*, x_R \rangle \rrbracket_G &:= \llbracket \langle x_R, (\hat{elt})^*, ?v_L \rangle \rrbracket_G \\
 \llbracket \langle x_L, (elt)^*, x_R \rangle \rrbracket_G &:= \begin{cases} \{\mu_\emptyset\} & \text{if } \exists \mu \in \llbracket \langle x_L, (elt)^*, ?v \rangle \rrbracket_G : \mu(?v) = x_R, \\ \emptyset & \text{else} \end{cases} \text{ and } \text{card}(\mu, \Omega) = 1
 \end{aligned}$$

Fig. 1 Standard semantics of SPARQL Property Paths, where $\alpha, \beta \in (\mathbf{I} \cup \mathbf{L} \cup \mathcal{V})$; $u, u_1, \dots, u_n \in \mathbf{I}$; $x_L, x_R \in (\mathbf{I} \cup \mathbf{L})$; $?v_L, ?v_R \in \mathcal{V}$; $?v \in \mathcal{V}$ is a fresh variable.

Function $\text{ALP1}(\gamma, elt, G)$
Input: $\gamma \in (\mathbf{I} \cup \mathbf{B} \cup \mathbf{L})$,
 elt is a PP expression,
 G is an RDF graph.

- 1: $Visited := \emptyset$
- 2: $\text{ALP2}(\gamma, elt, Visited, G)$
- 3: **return** $Visited$

Function $\text{ALP2}(\gamma, elt, Visited, G)$
Input: $\gamma \in (\mathbf{I} \cup \mathbf{B} \cup \mathbf{L})$, elt is a PP expression,
 $Visited \subseteq (\mathbf{I} \cup \mathbf{B} \cup \mathbf{L})$, G is an RDF graph.

- 4: **if** $\gamma \notin Visited$ **then**
- 5: add γ to $Visited$
- 6: **for all** $\mu \in \llbracket \langle ?x, elt, ?y \rangle \rrbracket_G$ such that $\mu(?x) = \gamma$ and
 $?x, ?y \in \mathcal{V}$ **do**
- 7: $\text{ALP2}(\mu(?y), elt, Visited, G)$

Fig. 2 Auxiliary functions used for defining the semantics of PP expressions of the form elt^* .

RDF ontologies. In this section we report some examples of SPARQL queries used to retrieve information from some ontology. Suppose to have a SPARQL dataset containing one or more ontologies, stored as named graphs.

Example 2: *Since, typically, every ontology contains at least one class, in this example we want to find all graphs that contain at least one class. This can be done in SPARQL by running the following query:*

```
PREFIX rdf: <http://www.w3.org/1999/02/22-rdf-syntax-ns#>
PREFIX owl: <http://www.w3.org/2002/07/owl#>
SELECT DISTINCT ?ontology
WHERE
{
  GRAPH ?ontology
    { ?c rdf:type owl:Class }.
}
```

In this example, the keyword GRAPH is followed by a variable (i.e., $?ontology$). Such a variable is used to bind the named graph for which the graph pattern is matched; in this case that contains at list one triple matching the triple pattern $?c \text{ rdf:type owl:Class}$.

Example 3: *Find all the subclasses of a given class. This can be done in SPARQL by running the following query:*

```
SELECT DISTINCT ?sc
WHERE
{
  ?sc rdfs:subClassOf :myClass.
}
```

Example 4: *Find all the subclasses of a given class, by making a recursive search. This means that the transitivity of the subclass relation must be made explicit. This can be done in SPARQL by running the following query that makes use of SPARQL property paths:*

```
SELECT DISTINCT ?sc
WHERE
{
  ?sc (rdfs:subClassOf)* :myClass.
}
```

Example 5: *Find the number of all classes of an ontology. The SPARQL query is the following:*

```
SELECT count(?c)
WHERE
{
  ?c rdfs:type owl:Class.
}
```

```
?c rdf:type owl:Class.  
}
```

This script can be easily modified to find the number of subclasses of a given class:

```
SELECT count(?sc)  
WHERE  
{  
  ?sc (rdfs:subClassOf)* :myClass.  
}
```

Example 6: Retrieve the information associated to the classes of an ontology. Below is the SPARQL query:

```
SELECT DISTINCT ?c ?p, ?o  
WHERE{  
  ?c rdf:type owl:Class.  
  {?c ?p ?o .}  
  UNION  
  {?o ?p ?c .}  
}
```

The UNION operator allows to consider both the triples in which the particular class appears as the subject and those in which it appears as the object.

Example 7: Find all the instances of a given class. It can be done by executing the following SPARQL query:

```
SELECT DISTINCT ?i  
WHERE{  
  ?i rdf:type :myClass.  
}
```

This query can be easily modified to find the instances of a given class or of all its subclasses. The following query uses a property path pattern:

```
SELECT DISTINCT ?i  
WHERE{  
  {?i rdf:type :myClass.}  
  UNION  
  {?i rdf:type ?c .  
   ?c (rdfs:subClassOf)* :myClass.  
  }  
}
```

Ontology Management Tools

There are a lot of software tools proposed for the creation and manipulation of ontologies. In what follows we provide a high level overview of the most popular ontology management tools. We will focus on the following three main aspects:

- Interoperability with ontology definition languages: considering the definition languages reported in the previous article (RDF, RDFS, OWL);
- Inference and consistency checking: discussing whether the tool has the possibility to use an inference engine and can perform constraint/consistency checking.
- Usability: by considering the existence of the graphical editors for the creation and querying of ontologies.

The result of the analysis is reported in [Table 2](#).

Protégé

Protégé ([Knublauch et al., 2004](#)) is a free, open source ontology editor and a knowledge management system developed at Stanford University. Protégé provides a graphical user interface to define ontologies. It also includes deductive classifiers to validate that models are consistent and to infer new information. Protégé currently exists in a variety of frameworks. A desktop system supports many advanced features to enable the construction and management of OWL ontologies. A Web-based system offers distributed access over the Internet using any Web browser.

Table 2 Comparison among various tools and environments for ontology development and engineering

<i>Tool</i>	<i>Input format</i>	<i>Output format</i>	<i>GUI</i>	<i>Consistency Checking</i>
Protégé	RDF(S), OWL	RDF(S), OWL	Yes	Yes
Swoop	RDF(S), OWL	RDF(S), OWL	Yes	Yes
OntoEdit	RDF(S)	RDF(S)	Yes	Yes
WebODE	RDF(S)	RDF(S)	Yes	Yes
KAON	RDF(S), OWL	RDF(S), OWL	No	Yes
DOE	RDF(S), OWL	RDF(S), OWL	No	Yes
NeOn	RDF(S), OWL	RDF(S), OWL	Yes	Yes

Swoop

Swoop ([Kalyanpur et al., 2006](#)) is an open-source, Web-based ontology editor and browser, tailored specifically for OWL ontologies. It supports multiple ontologies (so that entities and relationships across various ontologies can be compared, edited and merged), uses various OWL presentation syntax to render ontologies, and supports OWL reasoners for consistency checking. The layout of the GUI resembles a familiar frame-based website viewed through a Web Browser. It has formerly been maintained at the University of Maryland only, but is now jointly developed together with Clark & Parsia, IBM Watson Research and the University of Manchester

OntoEdit

OntoEdit ([Sure et al., 2002](#)) is an ontology editor integrating various aspects of ontology engineering, developed by Ontoprise, a provider of Semantic Web infrastructure technologies and product of Germany. Motivated by the fact that typically the development of ontologies involves collaborative efforts of multiple persons, it combines methodology-based ontology development with capabilities for collaboration and inferencing. OntoEdit has been developed by providing high extensibility through plug-in structure and an inference engine.

WebODE

WebODE ([Arpírez et al., 2001](#)) is an integrated ontological engineering workbench that helps users with ontology development and management activities such as ontology edition, browsing, learning, merge and alignment. Moreover, it includes middleware services that permit interoperation with other information systems, such as services for ontology library administration and access and ontology upgrading, querying, and metrics. WebODE is developed by the Technical School of Computer Science in Madrid, Spain.

KAON2

KAON2 (Karlsruhe ontology) ([Bozsak et al., 2002](#)) is an ontology infrastructure developed by the University of Karlsruhe, the Research Center for Information Technologies in Karlsruhe and the University of Manchester. Its first version (KAON1) was developed in 2002 and supported an enhanced version of RDF ontologies. In 2005, the second version (KAON2) was released, offering fast reasoning support for OWL ontologies. KAON2 supports answering conjunctive queries expressed using SPARQL syntax (even if not entire SPARQL specification is supported). Reasoning in KAON2 is implemented by algorithms that allow applying well-known deductive database techniques, such as magic sets or join-order optimizations.

DOE

Differential Ontology Editor (DOE) ([Bachimont et al., 2002](#)) is a simple ontology editor which allows the user to build ontologies via a particular methodology divided in three steps: (i) the user is invited to build two taxonomies of concepts and relations respectively, and for each notion he/she builds a definition following the principles that come from the Differential Semantics theory; (ii) the two taxonomies are considered from an extensional semantics point of view; (iii) the ontology can be translated into a knowledge representation language, which allows to use it in an appropriate ontology-based system or to import it into another ontology-building tool. DOE is developed by the National Audiovisual Institute in France.

NeOn

The NeOn Toolkit ([Haase et al., 2008](#)) aims at providing an infrastructure for networked ontology management and for engineering contextualized networked ontologies and semantic applications. It features methods and tools for managing knowledge that is distributed, heterogeneous, contextualized, and developed collaboratively. The NeOn Toolkit is open source and multi-platform and provides an extensive set of plug-ins covering a variety of ontology engineering activities such as development,

matching, reasoning and inference. The NeOn Toolkit was originally developed as part of the NeOn Project and is now supported by the NeOn Foundation.

Concluding Remarks

In this article, we have provided an overview of the SPARQL query language, a W3C standard. We have outlined the main features of the language via some examples and underlined both its pros (e.g., a flexible query language with specific supports for recursion) and cons (e.g., the fact that in its current form does not allow to perform automatic inference). In the last part, we provided an overview of popular ontology management tools.

Ontology in Bioinformatics

Pietro H Guzzi, University “Magna Graecia” of Catanzaro, Catanzaro, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Ontology is the study of existing entities or *things* there are in the universe (Sowa, 2000). In computer science, an ontology is defined as a specification of conceptualisations about a domain. Conceptualisation is the formalisation of knowledge about a domain, i.e., concepts, the relationships they hold, and the constraints between or among them. A specification is the concrete representation of this conceptualisation through the use of a formal language to represent knowledge, for example, description logic. So, an ontology is a shared understanding of some domain of interest, which is often realized as a set of **classes (concepts)**, **relations, functions, axioms, and instances** (Gruber, 1993a; Uschold *et al.*, 1998; Gruber, 1993b).

Formally, an ontology comprises:

- a set of strings describing lexical entries L for concepts and relations;
- a set of classes C representing the main concepts of the domain;
- a taxonomy of concepts with multiple inheritances (**heterarchy**) H_C ;
- a set of non-taxonomic relations R described by their domain and range restrictions;
- a heterarchy of relations, H_R ;
- a set of axioms A describing additional constraints on the ontology and making implicit facts explicit.

A class represents a set of entities or things within a domain, (e.g., protein and genes are concepts of the proteomics domain). Relations describe the interactions between two or more concepts or a concept's properties. The taxonomies of classes organise them into a tree-like structure.

For example, let us consider three concepts: (i) protein, (ii) molecule, a generalisation of the previous concept, and (iii) binding site, a portion of the three-dimensional structure of a protein deputed to link to another molecule. A simple type of organization can be imposed using the relations is a, has Component linking the concept in such a form: protein is a molecule, (specialization); protein has Component a binding site (association).

Even the relations, like concepts, can be structured into taxonomies, and they are annotated with specialized properties that capture some quantification, for example, a property that holds for all concepts, or for only one concept, or for a limited number of concepts belonging to a class.

Instances are the objects represented by a concept, for example, the P53 human protein is an instance of the concept of protein.

Axioms are constraints applied to the values of classes or instances, for example, a protein can have at least k PhosphorylationSite. The combination of an ontology and the instances of its concept is called a knowledge base.

Ontologies could be categorised by their characteristics, considering, for example, the levels of detail and generality of the proposed conceptualisation. Different works have proposed many guidelines to categorise ontologies, but for this study, we can consider only the level of generalisation in classifying ontologies. From these considerations, we can consider: (i) *top-level ontologies*, also known as foundational ontologies or standard upper ontologies (SUO), as formalized by the IEEE P1600.1 standard (see Relevant Website section), (ii) *generic ontologies*, and (iii) *domain ontologies*. The ontologies that belong to the first class contain specifications of the domain and problem-independent concepts and relations, such as the DOLCE Ontology (Gangemi *et al.*, 2003) or the Suggested Upper Merged 50 Ontology (SUMO) (Niles and Pease, 2001). The second class of ontology contains general knowledge about a certain domain, such as medicine or biology. The last class contains a specialised conceptualisation of a particular domain, for example, proteomics.

Languages for Modeling Ontologies

We will discuss only two languages specifically developed to model and reason on ontologies: the **Darpa Agent Markup Language plus Ontology Inference Layer** (DAML+OIL) (Hendler and McGuinness, 2001; Fensel *et al.*, 2001) and the **Ontology Web Language** (OWL) (Smith *et al.*, 2004) languages. Both ontology languages are based on **Resource Description Framework** (RDF) language. RDF (Decker *et al.*, 2000) is a standard for describing resources, i.e., anything that can be identified. RDF has been used as a data model to describe resources on the web. Its evolution, namely RDF Schema, allows the definition of elementary ontology elements, for example, classes and hierarchy, properties and constraints.

DAML was developed by the RDF Core Working Group to represent on-tological elements not captured by RDF. Successively, DAML was extended with OIL to enable the reasoning on ontologies. DAML+OIL consists of class elements, property elements, and instances, but was limited in its support of restrictions and concepts. Thus, Ontology Web Language (OWL) took the place of DAML+OIL as the semantic web standard.

OWL was developed from the concepts behind DAML+OIL and is the current W3C standard for ontology languages; it has been extended to provide more explicit description logic. OWL permits the writing of ontologies with different levels of

expressivity: OWL Lite, OWL DL, and OWL Full. The OWL syntax employs URIs for naming and implements the description framework for the web provided by RDF. Changes from DAML + OIL to OWL include the removal of DAML + OIL restrictions concerning RDF. OWL also supports the construction of distributed ontologies, which is beneficial in many ways.

Thus, the integration of distributed ontologies becomes an important design implication. Thus, the support of a distributed ontology system in which specialised ontologies can be maintained as separate entities becomes an attractive option. Moreover, in distributed environments, such as the GRID (Foster and Kesselman, 2003), the management of distributed ontologies can be helpful in addressing different problems.

Some Ontologies for Life Sciences

In this section, a representative sample of existing bio-ontologies will be presented. For this work, we will focus on ontologies used helping data analysis or querying. In the remainder of the section, we will discuss: (i) Gene Ontology (Ashburner *et al.*, 2000; Harris *et al.*, 2004), its usage in gene expression data analysis, (ii) TAMBIS Ontology (TaO) (Baker *et al.*, 1998; Paton *et al.*, 1999), the federation of different databases through its classes, and (iii) DAMON (Cannataro and Comito, 2003), a data mining ontology for grid programming.

The TAMBIS Ontology (TaO)

The Transparent Access to Multiple Bioinformatics Information (TAMBIS 95 Sources) system merges different biological databases through a common query interface on the web. The unification of such databases is realised by the use of an ontology called **TAMBIS ontology** (TaO), which describes bioinformatics tasks and resources. This ontology does not contain any instances, but only describes the application domain through its classes and properties. The instances 100 of this ontology are contained in external databases. In fact, TaO describes the resources, such as protein sequences, that are stored in the federated databases. For example, the concept of receptor protein represents the proteins with a receptor function, and the instances of this concept are the proteins stored in databases. In fact, a set of rules governs the joining of new concepts and the formation of relationships between them.

To explain the usage of TaO in such a system, let us consider a typical query that involves semantically different concepts. For instance, let us consider a user who starts a search by inserting the term *gene*. The system retrieves the relations that are connected to *gene*, (e.g., *hasAccessionNumber*, *AccessionNumber*, and *is Homologous*). This user can expand his or her query using the last terms producing this new concept (*Gene homologue of Gene with Accession Number*) that describes genes that are homologous to a gene with a particular accession number. The TAMBIS system takes this query and processes it, producing a set of queries for the external data sources.

Gene Ontology

The Gene Ontology project is maintained by the Gene Ontology (GO) Consortium. The consortium aims to develop a controlled vocabulary of the molecular-biology domain to describe and organise hierarchical concepts. Gene Ontology maintains the vocabularies of three domains: (i) molecular functions (GO:0008639, MF or F), (ii) biological processes (GO:0008150, BP or P), and (iii) cellular components (GO:0005575, CC or C). Moreover, every term has a unique identifier, for example, (GO:0000001), and a name.

The rationale of this classification is that this organizational structure can be applied to all living organisms, considering a generic eukaryotic cell. The first one is defined considering the biochemical level and what a product of a gene does. The second one mentions the biological goal. The biological process domain is not semantically equivalent to a biological pathway, as stated explicitly by the GO consortium. The last one references the place where a gene product plays its role. The vocabularies are often updated, so two types of terms have been introduced to manage the evolution. An **unknown term**, a child of the root of each vocabulary, it is meant to hold molecules that need more investigation to reveal their role in the domain. The term **obsolete** marks terms that have evolved and are no longer used in the domain.

The Gene Ontology vocabularies are structured hierarchically to form different directed acyclic graphs. In such a graph, a node corresponds to a biological term, and a directed edge links two nodes that are hierarchically related. This representation models the hierarchical structure like a tree, but allows multiple inheritances, i.e., each child node may have more than one parent (Ashburner *et al.*, 2000). Two types of parent-child relationships are defined in GO: *is-a*, and *part-of*. The first describes the specialization of a concept parent in its child. The second denotes that the child term is a component of the parent. A child term may have different relationships with its parents.

There exist many applications of GO in computational molecular biology and bioinformatics, such as Muro *et al.* (2006), Lu *et al.* (2004) and Zhang *et al.* (2004). For example, the GOSSIP framework (Bluthgen *et al.*, 2005) tests, statistically, whether the functions, processes, or locations described in the ontology could be significantly enriched by the use of a group of genes. The GOStat (Beissbarth and Speed, 2004) tool utilizes the information of GO to automatically infer what annotations are typical for a particular list of genes. The tool takes in input from a group of genes, finds the corresponding annotations in the ontology, and

generates statistics for each of these, considering, for example, over-representation. Finally, it sorts the GO terms according to their specificity to the considered group.

DAMON: A Data Mining Ontology for Grid Programming

The Data Mining Ontology for Grid programming (DAMON) (Cannataro and Comito, 2003) has been introduced to model data mining tools, concepts, and resources. DAMON aims to characterise the data mining scenario, considering the process of knowledge discovery in a distributed scenario, such as the GRID (Foster and Kesselman, 2003). The main goal of this ontology was to enable the semantic search of data mining resources and to suggest the use of the resources themselves. The conceptualisation has been made by these parameters:

Task: the data mining task performed by the software, for example, the results produced or the knowledge discovered;

Method: the type of methodologies that the software uses in the data mining process;

Algorithm: the algorithm that uses such methodologies;

Software: the software implementing the algorithms;

Data Source: the kind of data sources the software works on;

Human interaction the degree of required interaction with the user, for example, if the mining process is completely autonomous, or if it requires user intervention;

Suite: a collection of many types of data mining software tools.

Starting with these concepts, a set of taxonomies has been induced. Many non-taxonomic relationships and different constraints complete the 175 organization of concepts. For instance, the software and algorithm concepts are connected by **Implements Algorithm** property. This relationship has to verify some imposed constraints, for example, Implements Algorithm property of classification software must have a classification algorithm as filler.

By browsing DAMON, a researcher can choose the optimal data mining 180 techniques to utilize. Given a specified kind of data, a user can browse the ontology taxonomy and find the pre-processing phase, the algorithms, and its software implementation. In summary, the DAMON ontology allows the semantic search of data mining software and other data mining resources and suggests to the user the methods and software used to stored knowledge and the user's 185 requirements.

Biological and Medical Ontologies: Introduction

Marco Masseroli, Politecnico di Milano, Milan, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

Post-genomic era is producing an incredible amount of biological, bio-molecular and biomedical data, as well as a lot of valuable information extracted from them. This has increasingly stressed the need for more standardized ways to describe such information in order to be able to leverage on them to extract new biomedical knowledge. Many controlled vocabularies (i.e., terminologies) have been developed by different groups to define structural, functional, and phenotypic features of biomolecular and biological entities in a controlled way; more importantly, several of these terminologies are also being actively used world-wide to state and describe such features of specific genes, proteins, cells, tissues and even entire organisms, which are progressively becoming more and better known. This has produced and is keeping generating a growing corpus of precious controlled information; yet, the proliferation of different terminologies, often regarding the same or similar topics, has created the absolute necessity to identify equivalences, similarities, and in general relations between the terms used in different controlled vocabularies, triggering the development of mapping efforts among them. On the other hand, the need to more properly describe the increasing knowledge about the complex biomolecular and biomedical domains in a way that would allow to take advantage of it also computationally, prompted the definition of semantic relations between the terms within these controlled vocabularies, with the development of a number of biomolecular and biomedical ontologies; some of them have become widely used to describe the features of the biomedical-molecular entities in different databases, representing a key element for the interoperability of these repositories.

After this introduction, this article first illustrates what an ontology is and what is its relevance from the knowledge discovery point of view. Then, it focuses on the terminologies and ontologies in the life science domain, highlighting their main issues. Finally, it describes and discusses two important mapping and interoperability efforts among many terminologies and ontologies in the biomedical and biomolecular domains, whose main ones are individually described in the following sections.

Terminologies and Ontologies

A *controlled vocabulary*, or *terminology*, is a collection of the precise and universally comprehensible terms that univocally define and identify different concepts in a specific subject field or domain of activity. Terms are single words, compound words, or multi-word expressions that in a specific context (i.e., domain) have specific meanings; such meanings may be different from those that the same terms have in other contexts. Thus, a terminology regards the concepts in a specific domain and the labels (terms) used in that domain to refer to them. Particularly, such terms are controlled since they are defined and maintained by groups of experts of the specific domain of the terminology.

In a terminology, the concepts are defined as independent and unrelated, however often semantic relations exist between the concepts used in a domain; such relations can be expressed through *semantic networks*. They are logical structures used to represent relationships between concepts in a specific domain through a graph structure; such structure is composed of a set of elements, the graph nodes, representing the domain concepts, and the graph arches, representing the relations between the domain concepts. Each arch in the graph defines a type of relation; the main relation types are *IS A* and *PART OF*. The former one describes a *specification*, and defines a subtype of a concept or class (e.g., a growth factor *IS A* protein). The latter one expresses *membership* and represents a part-whole relationship; it relates two concepts A and B only if B is part of A whenever B is present and its existence implies the existence of A, although the presence of A does not guarantee the presence of B (e.g., a gene is *PART OF* DNA, since all genes are part of some DNA).

IS A and *PART OF* model hierarchical relations, with concepts related at different levels of specification. Both of them held the transitive property, which can be used to make useful inferences. Furthermore, the *IS A* relation allows the inheritance of attributes among related concepts, i.e., all attributes of a more general concept apply also to a more specific one, related to the former one through an *IS A* relation.

Other more specific relations present in the biomedical-molecular domain are: *ASSOCIATED WITH*, *EXPRESSED BY*, *REGULATED BY*, *TREATED BY*, *CAUSED BY*, etc.

Semantic networks are also a reasoning tool, since they allow finding relations between concepts which are not directly related. For example, through a semantic network which expresses that the *DNA* is *PART OF* a *cell*, and a *cell* is *PART OF* an *organism*, it can be inferred that the *DNA* is *PART OF* an *organism*, although in the semantic network it is not explicitly expressed (i.e., there is no a direct relation between *DNA* and *organism*) (Fig. 1). Interestingly from a computational point of view, semantic networks can be implemented in software and automatically processed, i.e., knowledge inference can be performed automatically.

An *ontology* is a semantic structure used to describe the knowledge of a domain in a textual and computable form, as well as standardize and give precise definitions for the terminology employed in the domain. According to the philosopher Barry Smith, it is "any theory or system that aims to describe, standardize or provide rigorous definitions for terminologies used in a domain" (Smith, 2003).

Fig. 1 Example excerpt of the DAG of an ontology in the biomolecular domain, with its semantic network relating concepts defined by the ontology controlled vocabulary.

Ontologies are composed by a controlled vocabulary (i.e., terminology) and a semantic network; leveraging on the latter one, they are very useful for automatic classification, inference and reasoning. They are generally represented through a Directed Acyclic Graph (DAG), where the DAG nodes are the domain concepts expressed by the ontology controlled vocabulary, and the DAG edges are the semantic relations between them, described by the semantic network of the ontology (Fig. 1). Since in a DAG relations are directed, a hierarchy exists among the concepts of the ontology, where one of two related concepts is more general (i.e., the parent) and the other more specific (i.e., the child). In a DAG not only a parent node can have multiple children, but also a child node can have multiple parent nodes; this is the main aspect that differentiates a DAG from a tree. The simplest version of an ontological DAG is a logical tree; in this case, when all relationships of the ontological tree are of IS A type, the ontology is a taxonomy.

Bio-Terminologies and Bio-Ontologies

When a terminology or an ontology regards the biological, biomolecular, or biomedical domain, it is said to be a bio-terminology or bio-ontology. While the aim of a bio-terminology is to collect names of entities (i.e., substances, qualities and processes) used in the life sciences, the purpose of a bio-ontology is to characterize classes of entities, existing in the reality, which are of biological/biomedical significance; thus, a bio-ontology is concerned with the principled definition of biological, biomolecular, or biomedical classes, and the relations among them.

Bio-terminologies and bio-ontologies have an important role in e-science, since they provide formal and explicit declarations of the entities and their relationships in the life sciences. Built by humans, they can be automatically processed by machines; they have the capabilities of relating disparate data and enabling data interoperability (Fig. 2), data summarization, and data mining. They favor information and knowledge management, sharing, and analysis through the integration of sparse and heterogeneous information, the identification and grouping of “similar” bio-entities, as well as the statistical analysis and data mining of their controlled descriptions. In doing so, they can highlight most relevant biological/biomedical features, and help unveiling knowledge from data; furthermore, they support translational research, to quickly bring in the clinical practice new biomolecular knowledge.

Several bio-terminologies and bio-ontologies have been and are being developed and used to define, describe and suitably identify life science information. They are increasing in number, coverage and use in molecular biology and biomedicine; some notable examples, among the many that should be cited, regard biomolecular sequences (Sequence Ontology (Cunningham *et al.*, 2015)), Protein Ontology (Natale *et al.*, 2017), protein families and domains (Pfam (Finn *et al.*, 2014), InterPro (Finn *et al.*, 2017)), biological processes, molecular functions, cellular components (Gene Ontology (Ashburner *et al.*, 2000)), biochemical and metabolic pathways (KEGG (Ogata *et al.*, 1998), Reactome (Fabregat *et al.*, 2016)), genetic diseases (OMIM (Hamosh *et al.*, 2005), Disease Ontology (Schröml *et al.*, 2012)), and phenotypes (Human Phenotype Ontology (Köhler *et al.*, 2016)). They are very useful to enrich lists of genes and gene products with biological and biomedical information, in a way that then such lists and information can be automatically processed and effectively used in computational evaluations, also based on data mining and machine learning approaches.

Bio-Ontology Issues

Bio-ontology development is fragmented: separate communities of biomedical researchers create and maintain diverse ontologies, and different model organism databases use diverse ontologies to annotate their experimental data. When these activities are not

Fig. 2 Ontology driven interoperability of bio-knowledge databases.

unified, they produce not matching ontologies, and consequently not comparable annotations; whereas, unification of efforts could allow integration of each other and with other data, as well as cross-species analyses, also thanks to the algorithms that bioinformaticians are creating to analyze these valuable ontological annotations.

Problems exist at both ontology curation and experimental data annotation level. For ontology content curation, the faced issues rise from many different groups/consortia creating ontologies with uncoordinated efforts, and many different ontologies overlapping in content and with variable quality. This ends in having ontologies that are not interoperable; a strong limitation that can be smoothed only through ontology (and terminology) mapping efforts, which however are laborious and time consuming. Thus, instead of driving interoperability, as they are supposed to do, available ontologies become barriers to accessing, effectively using, and expanding data repositories.

Regarding experimental data annotation (i.e., controlled description of experimental data features), a growing number of data in biomedical resources are annotated with ontologies (e.g., Gene Ontology, Disease Ontology), but current data resources are confined to use single ontology for annotations. Furthermore, issues to be faced concern the difficulty to relate different annotation repositories to each other, with data integration efforts made laborious by mapping difficulties.

With the aim of overcoming these issues, the US National Institute of Health (NIH) funded the National Center for Biomedical Ontology (NCBO), with the mission to advance biomedicine with tools and methodologies for the structured organization of knowledge. Its strategy is to develop, disseminate, and support open-source ontology development and data annotation tools, as well as resources enabling scientists to access, review, and integrate disparate knowledge resources in biomedicine. NCBO supports biomedical researchers in their knowledge-intensive activities, by giving online tools and a Web portal allowing them to access, review, and integrate diverse ontological resources in all aspects of biomedical research and clinical practice. A major focus regards the use of biomedical ontologies to aid in the management and evaluation of data from complex experiments. Among the tools and resources provided by the NCBO, the main ones are:

1. *Open Biological and Biomedical Ontologies* (OBO): An integrated virtual library of biomedical ontologies
2. *Open Biomedical Database* (OBD): An online repository of OBO annotations on experimental data accessible via BioPortal
3. *BioPortal*: A Web-based portal to allow investigators and intelligent computer programs to access the OBO, use them to annotate experimental data in OBD, and visualize and analyze OBO annotations in OBD.

Open Biological and Biomedical Ontologies

The OBO are a set of well-structured, orthogonal, fully interoperable, reference ontologies for shared use across different biological and medical domains; they get these great features by virtue of a common design philosophy and implementation, with sharing principles, including the use of a unique identifier space and enclosure of definitions for all ontology concepts. They were created, and are developed and maintained, by the OBO Foundry, an open, inclusive and collaborative experiment engaging developers of science-based ontologies, which is involved in establishing principles for proper ontology development, and applying them in the OBO (Smith *et al.*, 2007). Mission of the OBO Foundry is developing a family of interoperable ontologies which are both logically well-formed and scientifically accurate to incorporate precise representations of the biological reality. Furthermore, it aims at fostering interoperability of ontologies within the wider OBO framework, and also guaranteeing a gradual improvement of quality and formal rigor in bio-ontologies. The Foundry supports community members who are developing and publishing ontologies in the biomedical domain, so that the created and used ontologies enable scientists and their instruments to communicate with minimum ambiguity.

The OBO Foundry provides a new paradigm for biomedical ontology development by creating gold standard reference ontologies for individual domains of investigation. In order to be part of OBO, an ontology must satisfy several requirements, i.e., it

must be: (i) *open*, i.e., accessible to everyone without any constrain other than its origin must be recognized and its subsequent modifications must be distributed under different names and identifiers; (ii) *expressed in a common and shared syntax and relations* (i.e., using a formal language in an accepted concrete syntax such as the OBO syntax (see in Relevant Websites), its extension, or Web Ontology Language (OWL) (Knublauch *et al.*, 2006)), in order to ease use of the same tools and shared implementation of software applications; (iii) with a *unique identifier space* within OBO; (iv) *clearly specified* and with a *well defined content*, with each OBO ontology that must be orthogonal to the other OBO ontologies; (v) *not overlapping other OBO ontologies* (although partial overlapping can be allowed in order to enable combination of ontology terms to form new terms); (vi) *strictly-scoped in content*, i.e., the ontology scope must be clearly specified and its content must adhere to that scope; (vii) *able to include textual definitions of all terms*, i.e., since several biomedical terms can be ambiguous, the concepts they represent must be precisely defined with their meaning within the specific ontology domain they refer, which must be also specified; (viii) using *relations* which are *unambiguously defined* and follow the pattern of definitions characterized in the OBO Relation Ontology (Guardia *et al.*, 2012); (ix) *well documented*; (x) *collaborative*, i.e., its development must be carried out in a collaborative way; and (xi) with a *plurality of independent users*.

Furthermore, all ontologies that are part of the OBO standard must discriminate:

1. continuants (cells, molecules, organisms, ...)
2. occurrents (events, processes)
3. dependent entities (qualities, functions, ...)
4. independent entities (their bearers)
5. universals (types, kinds)
6. instances (tokens)

This is performed also thanks to the many semantic relations defined between OBO concepts; examples of the different semantic types of such relations included in OBO, and thus that are common to all the ontologies that share the OBO standard, are the *foundational* (is a, part of), *spatial* (located in, contained in, adjacent to), *temporal* (transformation of, derives from, preceded by), and *participation* (has participant, has agent) types.

OBO ontologies tackle several different biological and biomedical aspects, including organism taxonomies, anatomies, cell types, genotypes, sequence attributes, temporal attributes, phenotypes, diseases, and others. The most developed and used OBO include the Gene Ontology (Ashburner *et al.*, 2000), Cell Ontology (Meehan *et al.*, 2011), Foundational Model of Anatomy (Rosse and Mejino, 2003), Disease Ontology (Schriml *et al.*, 2012), Human Phenotype Ontology (Köhler *et al.*, 2016), Phenotypic Quality Ontology (Gkoutos *et al.*, 2005), Sequence Ontology (Cunningham *et al.*, 2015), Protein Ontology (Natale *et al.*, 2017), Relation Ontology (Guardia *et al.*, 2012), Ontology for Biomedical Investigations (Bandrowski *et al.*, 2016), etc.; some of them are detailed described and discussed in the next sections.

Unified Medial Language System

The Unified Medial Language System (UMLS) (Bodenreider, 2004) is another extremely relevant effort to overcome the important issues deriving from the dispersed and unsynchronized works devoted to the development of terminologies and ontologies in the biomedical domain, which consequently result not interoperable. Designed, maintained and disseminated by the National Library of Medicine (NLM), a division of the US National Institute of Health (NIH), since the 1986 the UMLS is an evolving mapping endeavor among the major terminologies and ontologies used in the biomedical and biological domain, with updates twice a year. Its goal is to provide support for the integration of biomedical textual annotations scattered in distinct databases and biomedical resources; its major aim is to overcome two significant barriers towards the effective retrieval of machine-readable information: i) the variety of ways the same concepts are expressed in different machine-readable sources and by different people, and ii) the distribution of useful information among many disparate databases and systems. Other UMLS aims are: facilitating the communication between different biomedical systems, supporting information retrieval and medical record systems, enhancing the access to the biomedical literature by facilitating the development of computer systems that understand biomedical language, developing automatic systems for parsing the biomedical literature, and building enhanced electronic information systems able to create, process, retrieve, integrate, and/or aggregate biomedical and health data and information, both for clinical and informatics research. UMLS strategy towards these goals and aims is providing a set of multi-purpose tools for system developers, i.e., the UMLS is not an end-user application, but enhances the possibility to develop effective end-user applications. UMLS approach is based on leveraging on Knowledge Sources to overcome disparities in language and language format (e.g., *atrial fibrillation*, vs. *auricular fibrillation*, vs. *af*), as well as disparities in granularity (e.g., *contusions*, vs. *hematoma*, vs. *bruise*) and perspective (e.g., when instructing a patient to promptly report *excessive bruising* and *nosebleeds* instead of *epistaxis*). Among UMLS key points there are a broad coverage of medical terms and the absence of multiple inheritance (i.e., each term has only a parent).

UMLS Content and Main Activities

UMLS is a compendium of many controlled vocabularies used in the biomedical domain, which provides a mapping structure among these vocabularies and allows the translation of a term among the various terminology systems mapped (Fig. 3). It may also be viewed as a comprehensive thesaurus and ontology of biomedical concepts.

Fig. 3 (a) UMLS as a mapping structure among many biomedical controlled vocabularies. (b) UMLS as a tool for the translation of a term among mapped terminologies.

UMLS organizes terms and concepts of all the mapped controlled vocabularies and ontologies, as well as relates them to other concepts, and categorizes them in broader concepts.

It organizes terms by clustering synonymous terms into a concept, and for each of such concepts it identifies a *preferred term* and a *concept unique identifier* (CUI) (Table 1).

UMLS also organizes concepts described in multiple ontologies with different hierarchies, by using one graph instead of multiple trees (multiple inheritance); in doing so, it keeps inter-concept relations existing in the different hierarchies from the original ontologies, representing redundancy with multiple paths (Fig. 4(a) and (b)).

Furthermore, UMLS relates the organized concepts also to other concepts, through additional hierarchical relationships (i.e., linking to other trees, or making relationships explicit), non-hierarchical relationships, relations to co-occurring concepts, or through relationships' mapping.

Finally, it categorizes concepts by defining high-level categories (*semantic types*) assigned by the UMLS editors independently on the hierarchies where the concepts are located (Fig. 5).

As an example, Fig. 6 shows the representation of the *Addison's disease* concept in UMLS, with its many synonyms, eponyms and clinical variants in different medical vocabularies, and also in different languages, and with its definition, CUI, and semantic type.

Table 1 Example of different synonymous terms in distinct controlled vocabularies for the concept with UMLS preferred term Addison's disease and CUI C0001403

Term	Vocabulary	ID
Addison Disease	MeSH	D000224
Primary hypoadrenalism	MedDRA	10036696
Primary adrenocortical insufficiency	ICD-10	E27.1
Addison's disease (disorder)	SNOMED CT	363732003
Bronzed disease	SNOMED International	DB-70620

Fig. 4 (a) UMLS single graph approach to describe concepts and their relations in multiple different hierarchies. (b) Example application to the Addison's disease and its relations in the SNOMED CT, SNOMED International, MeSH, and MeDRA hierarchies.

Fig. 5 Example of Disease or Syndrome semantic category applied to the Addison's Disease UMLS concept.

Fig. 6 Example of a concept in UMLS: Addison's Disease.

To perform all these activities (i.e., clustering synonymous terms into concepts, defining a concept unique identifier, refining granularity, broadening scope, adding hierarchical relationships, and providing semantic categorization), UMLS takes advantage of UMLS editors' activity, available lexical knowledge, and semantic pre-processing; the latter one takes into account also the metadata in the source vocabularies, and positive (or negative) evidence for tentative synonymy relations based on lexical features, providing an automatic tentative categorization which is then revised by the UMLS editors.

UMLS Knowledge Sources

The UMLS is composed of three main parts: *Metathesaurus*, *Semantic Network*, and *SPECIALIST Lexicon*, which constitute the UMLS Knowledge Sources, as well as of several *lexical tools*. By design, the UMLS Knowledge Sources are multi-purpose, i.e., they are not optimized for particular applications, but can be applied in systems that perform a range of functions involving one or more types of information (e.g., patient records, scientific literature, guidelines, and public health data).

UMLS Metathesaurus

The UMLS *Metathesaurus* contains information about biomedical and health related concepts, their various names and associated codes, and the relationships among them. It covers a wide range of general and specialized biomedical terminologies, and constitutes the base of UMLS biomedical concepts and their names. It is very large, including at the time of writing this article nearly 3.5 million of biomedical concepts (133 semantic types), more than 13.5 millions of concept names, and 8 millions of relationships (54 semantic relationships); it is multi-source (150 sources), multi-lingual (25 languages), and multi-purpose. The contained source vocabularies and classifications are of many different types, comprising general vocabularies (e.g., RxNorm for drugs), clinical vocabularies, some in multiple languages (e.g., SNOMED CT), administrative code sets (e.g., ICD-9-CM, CPT), and thesauri used to index and retrieve scientific literature and biomedical information in general (e.g., MeSH, CRISP, NCI).

The Metathesaurus is used in a variety of settings and purposes, such as clinical, administrative, public health reporting, and research; its uses span information retrieval, thesaurus construction, natural language processing, automated indexing, and

electronic medical / personal health records. It is organized by concept; each concept has specific attributes defining its meaning, and is linked to the corresponding concept names in the various source vocabularies. Numerous relationships are represented between the concepts, including hierarchical relationships (i.e., *is a*, *is part of*), and associative relationships (e.g., *is caused by*, *in the literature often occurs close to*). It clusters terms from multiple sources by meaning, assigns them to a single concept for which it defines a Concept Unique Identifier, chooses the concept preferred term (as a default, which can be changed), and sets concept synonymous terms (Table 1).

UMLS Semantic Network

Each concept in the Metathesaurus is assigned to one or more semantic types, linked each other through semantic relationships; they broadly and consistently categorize the biomedical domain, and form the UMLS *Semantic Network*, which includes 133 semantic types and 54 semantic relationships.

Semantic types define broad, high level subject categories such as *Clinical Drug*, or *Virus* (e.g., *Disease or Syndrome* is the semantic type of the concept *Addison's Disease*); they are assigned to Metathesaurus concepts independently of concept position in source hierarchies. The major upper level semantic types regard entities (i.e., *Physical object*, or *Conceptual entity*) and events (i.e., *Activity*, *Phenomenon* or *Process*); the main physical object types are *Organism*, *Anatomical structure*, *Manufactured object*, and *Substance*. Major groupings of semantic types comprise *Organism*, *Anatomical structure*, *Biologic function*, *Chemical*, *Physical object*, *Idea or concept*. The information about each semantic type includes a unique identifier, a tree number that represents its position in an *is a* hierarchy, a definition, examples, and its related parent and children types.

Semantic relationships are links between semantic types, such as *is a*, *causes*, or *treats* (e.g., *Virus causes Disease or Syndrome*). They define the structure of the semantic network, and represent important relationships in the biomedical domain between concept categories and between concepts; thus semantic relationships may hold also at the concept level, where also other relationships may apply.

The primary semantic relationship is the *is a*, which establishes a hierarchy of types within the Semantic Network, either among types (e.g., *Animal is a Organism*, *Enzyme is a Biologically active substance*, *Mental process is a Physiological function*), or among relationships (e.g., *prevents is a affects*); furthermore, it eases the allocation of the most specific semantic type available for a Metathesaurus concept.

The Semantic Network also has five major categories of non-hierarchical (or associative) relationships, which group the remaining 53 semantic relationships; these five categories are *physically related to*, *spatially related to*, *temporally related to*, *functionally related to*, and *conceptually related to*. Examples of non-hierarchical relationships are *diagnoses* (e.g., *Sign or Symptom diagnoses Pathologic function*), and *treats* (e.g., *Pharmacologic substance treats Pathologic function*).

The information about each semantic relationship includes a unique identifier, a digit number representing its position in an *is a* hierarchy, a definition, examples, and the set of semantic types that can be linked by the relationship.

UMLS Specialist Lexicon

The *SPECIALIST Lexicon* is a syntactic English lexicon of common words and biomedical terms, which includes at the time of writing this article more than 250 thousand words, and more than 400 thousand variants. It contains information about common English vocabulary, biomedical terms, terms in MEDLINE (PubMed), and terms in the UMLS Metathesaurus. Each of its entries contains *morphological information* (word form and structure, i.e., inflection or derivation), *orthographic information* (word spelling, i.e., spelling variants), and *syntactic information* (how words are put together, i.e., complementation of verbs and nouns) (Table 2).

It is used by the *SPECIALIST Natural Language Processing* system to process text and terms in a customizable way, which is employed to maintain Metathesaurus, indexes.

UMLS Lexical Tools

UMLS *lexical tools* are software programs, in Java programming language, to manage lexical variation, indexing, and normalization in biomedical text. They aim to assist developers in customizing or using the UMLS Knowledge Sources for particular purposes; for example, researchers can use the UMLS products in investigating knowledge representation and retrieval questions. The main lexical tools are Wordind, Lexical Variant Generation, NORM, and MetaMap.

Wordind creates word indexes by breaking a text string into a unique list of lowercased words, whereas *Lexical Variant Generation* (LVG) (Divita et al., 1998) generates normalized terms for word indices, by performing various atomic lexical transformations producing inflectional variants (e.g., the input terms *swim*, *swam*, and *swum* all normalize to the term *swim*).

NORM is a lexical program that generates the normalized strings for the terms in the *SPECIALIST Lexicon*; it includes a selection of LVG transformations, and produces Metathesaurus normalized word and string indexes used to access those terms. The normalization process involves many steps, including stripping possessives, replacing punctuation with spaces, removing stop words (e.g., "No Other Specification" or NOS), lower-casing each word, breaking a string into its constituent words, and sorting the words in alphabetic order.

MetaMap (Aronson, 2001) automatically maps biomedical text to concepts in the UMLS Metathesaurus, i.e., it finds Metathesaurus concepts in text. It does it through a set of subsequent steps which include parsing (using *SPECIALIST* minimal commitment parser, *SPECIALIST Lexicon* and a part of speech tagger), variant generation (using *SPECIALIST Lexicon*, and *Lexical Variant Generation*), candidate concept retrieval (from the Metathesaurus), candidate concept evaluation, and mapping construction. A distributable version of *MetaMap* is available with the name *MetaMap Transfer* (MMTx).

Table 2 Type of information provided for each word in the UMLS SPECIALIST Lexicon

<i>Morphological information</i>	
<i>Word inflection</i>	
Noun:	Nucleus, nuclei
Verb:	Cauterize, cauterizes, cauterized, cauterizing
Adjective:	Red, reddest, redder
<i>Word derivation</i>	
Verb <-> noun:	Cauterize <-> cauterization
Adjective <-> noun:	Red <-> redness
<i>Orthographic information</i>	
<i>Word spelling variants</i>	
oe/e:	Oesophagus–esophagus
ae/e:	Anaemia–anemia
ise/ize:	Cauterise–cauterize
Genitive mark:	Addison's disease Addison disease Addisons disease
<i>Syntactic information</i>	
<i>Word complementation</i>	
<i>Verbs</i>	
Intransitive:	I'll treat
Transitive:	He treated the patient
Ditransitive:	He treated the patient with a drug
<i>Nouns</i>	
Prepositional phrase:	Valve of coronary sinus

UMLS Availability

UMLS can be freely used both locally and remotely. The former access mode is available through the MetamorphoSys software, by installing files locally, and creating customized Metathesaurus subsets that can then be searched, browsed, and viewed. The latter access mode is available via the UMLS Terminology Services (UTS), which provide UMLS Metathesaurus and Semantic Network browsers, as well as application programming interfaces (APIs), downloadable files and programs, guides and documentation to UMLS resources. UTS purpose is to make the UMLS resources more accessible to both users and systems developers.

The use of the UMLS resources, both locally and remotely, is subject to the sign of an online Web-based license, which is free, but with some limitations, particularly in its appendices.

Biographical Sketch

Marco Masseroli received the Laurea degree in Electronic Engineering in 1990 from Politecnico di Milano, Italy, and the PhD degree in Biomedical Engineering in 1996, from the Universidad de Granada, Spain. He is associate professor in the Dipartimento di Elettronica, Informazione e Bioingegneria at Politecnico di Milano, and lecturer of Bioinformatics and Biomedical Informatics. He carried out research activity in the application of Information Technology to the medical and biological sciences in several Italian and international research centers. He has also been visiting professor in the Departamento de Anatomía Patológica, Facultad de Medicina at the Universidad de Granada, Spain, and visiting faculty at the Cognitive Science Branch of the National Library of Medicine, National Institute of Health, Bethesda. His research interests are in the area of bioinformatics and biomedical informatics, focused on distributed Internet technologies, biomolecular databases, controlled biomedical terminologies and bio-ontologies to effectively retrieve, manage, analyze, and semantically integrate genomic information with patient clinical and high-throughput genetic data. He is the author of more than 170 scientific articles, which have appeared in international journals, books, and conference proceedings.

Biological and Medical Ontologies: GO and GOA

Marco Masseroli, Politecnico di Milano, Milan, Italy

Introduction

Many ontologies exist to describe concepts and their relationships in biology; the Gene Ontology (GO) (Ashburner *et al.*, 2000) is the most developed and used one. This article focuses on this paramount ontology, first describing its development, composition, structure, included concepts and relations, as well as their amounts, available formats and the tools available to browse them. Then, it shows the annotations that can be provided through the GO, and the ways to define their supporting evidence and rules to express them. Furthermore, it illustrates the relevant use of such annotations in computational applications, and the available repositories containing them. Finally, it describes and discusses issues still present in the GO and their possible solutions.

The Gene Ontology

Out of the many ontologies available to describe concepts and their relationships in biology, the Gene Ontology (GO) (Ashburner *et al.*, 2000) is the most developed and used one. The GO project was born in November 1998 as a collaborative effort among the databases of three model organisms: FlyBase (*Drosophila*), *Saccharomyces* Genome Database (SGD) and the Mouse Genome Database (MGD). It addresses the necessity to have consistent descriptions of gene products across databases, in order to ease the search for all available information regarding the same biological entity, but stored in different databases, and to be able to compare them and to support comparative genomic and proteomic studies. This important task, common to almost all biological studies, is difficult due to the dispersion of the information in many distributed and heterogeneous resources, often using different data organizations. Additionally, it is hampered by the use of multiple different terms in distinct databases to describe the same concept or entity, and also the same term to address different concepts, particularly in different species; this prevents obtaining effective results through automatic searches, and even by not highly expert human beings. As an example, the different terms “protein synthesis” or “translation” are equally used to refer to the same biological process of protein production; conversely, the same term “bud initiation” is equally used to refer to the initial area of outgrowth from a cell in the formation of a new cell, or the primordial structure from which a tooth is formed (in animals), or the embryonic shoot of a new branch (in plants).

Since its constitution, the GO Consortium (GOC) has incorporated an increasing number of databases, including many of the most relevant repositories for plant, animal, and microbial genomes. On the basis of the variety of biological entities of different organisms contained in such databases, it has developed three associated sub-ontologies (i.e., structured controlled vocabularies and the relationships between the concepts described by their terms) that express, in a species-independent manner, the *biological processes*, *cellular components*, and *molecular functions* in which the biological entities of different organisms are involved. Specifically, the cellular component sub-ontology describes the parts and the extracellular environment of cells, the molecular function sub-ontology defines the gene product basic activities at molecular level (e.g., binding or catalysis), and the biological process sub-ontology characterizes the operations or the sets of molecular events with a defined start and stop which regard the functioning of integrated living units (e.g., cells, tissues, organs, and organisms). Thus, these three ontologies, which are encompassed within the GO and constitute its sub-ontologies, are very effective in expressing the functional characteristics of genes and proteins across organisms, eukaryotic and single or multi-cellular prokaryotic organisms, even as knowledge keeps accumulating and evolving (Ashburner *et al.*, 2000).

GO Structure

Within each GO sub-ontology, the concepts that the GO terms define and the relationships between them form a logical structure, named Directed Acyclic Graph (DAG) (Fig. 1), which is a graph made of nodes and edges.

Within the GO DAG, each node represents a single concept (i.e., a GO category) expressed by a unique *term* of the controlled vocabulary, whose *name* may be a word or string of words. A term may have one or more *synonyms*, which represent other word or phrase forms to express exactly the same or a close concept, with indication of the relationship between the term and the synonym given by the synonym scope (i.e., EXACT, BROAD, NARROW, or RELATED); furthermore, a term may have one or more *references* to equivalent concepts in other databases (*xref*), and a *comment* about the term meaning or use. Each GO DAG node is identified by a unique alphanumeric *identifier* (ID), formed by the “GO:” characters followed by seven digits (e.g., GO:0033926); furthermore, each DAG node has a unique *definition* with cited sources (e.g., [EC:3.2.1.108], to the ExPASy Enzyme database), and a *namespace* specifying the sub-ontology to which it belongs. An example of the elements of a GO DAG node is the following:

identifier: GO:0033926.

name: glycopeptide alpha-N-acetylgalactosaminidase activity.

namespace: molecular_function.

Fig. 1 Example of Gene Ontology Directed Acyclic Graph, for the GO term 'cell aging' (GO:0007569).

definition: "Catalysis of the reaction: D-galactosyl-3-(N-acetyl-alpha-D-galactosaminyl)-L-serine + H₂O=D-galactosyl-3-N-acetyl-alpha-D-galactosamine + L-serine." [EC:3.2.1.97].

synonym: "D-galactosyl-N-acetyl-alpha-D-galactosamine D-galactosyl-N-acetyl-galactosaminohydrolase activity" EXACT [EC:3.2.1.97].

synonym: "endo-alpha-acetylgalactosaminidase activity" BROAD [EC:3.2.1.97].

synonym: "endo-alpha-N-acetylgalactosaminidase activity" BROAD [EC:3.2.1.97].

xref: EC:3.2.1.97.

xref: MetaCyc: 3.2.1.97-RXN.

xref: InterPro: IPR024746.

xref: InterPro: IPR025706.

Each edge of the GO DAG connects two nodes of the same GO sub-ontology, or sometimes of different GO sub-ontologies, and represents a relation between the linked nodes/concepts, i.e., between the vocabulary terms that express them.

As its name indicates, there are no cycles between the nodes of a DAG, and its edges have a one-way meaning. This allows classifying the DAG nodes in top-level, mid-level, and bottom-level nodes, where the level denotes the grade of specialization of each node, being upper-level nodes the most generic and lower-level ones the most specialized. Thus, a DAG is very similar to a hierarchical tree structure; yet, differently from a hierarchy, in a DAG a "child" node, i.e., a more specialized concept, can have multiple "parents" nodes, i.e., more generic concepts, related to it through different types of relations. This defines different paths from a DAG node to the DAG root-node (that is unique), which can be formed by a different number of mid-level nodes (Fig. 2); thus, the notion of level of a DAG node is not unique, since a DAG node can be at different levels simultaneously.

GO relations

Any number of relations can exist between two nodes of the GO DAG, and each of such nodes can have any number and type of relations to other nodes in the GO graph. Currently, the relations described in the Gene Ontology are mainly hierarchical of two types: *specification* (i.e., the *IS A* relation) and *membership* (i.e., the *PART OF* relation).

The *IS A* relation constitutes the main structure of the GO DAG. It defines a subtype, not an instance, i.e., not a specific example of something; in fact, GO terms represent classes of entities or phenomena, rather than specific manifestations thereof, which are defined through the annotation of such manifestations with the GO terms. Examples are: *mitotic cell cycle IS A cell cycle*, or *lyase activity IS A catalytic activity*.

The *PART OF* relation represents a part-whole relationship. In the GO it relates two concepts A and B only if B is necessarily part of A whenever B exists, and its presence implies the presence of A; yet, the existence of A does not mean for certain the presence of B. An example is: *replication fork PART OF chromosome*, since all replication forks are part of some chromosome (but only some chromosomes have a replication fork as their part).

Other kinds of relations that are present, although limitedly, in the GO are *HAS PART*, *REGULATES* and *OCCURS IN*.

HAS PART is the logical counterpart of the *PART OF* relation; it represents a part-whole relationship from the view point of the whole. As *PART OF*, it is used to relate two concepts A and B only when A always necessarily has B as a part; yet, if B exists, it does not mean for certain that A exists. For example: *nucleus HAS PART chromosome*, since all nuclei contain a chromosome, although only some chromosomes are part of a nucleus.

Fig. 2 Example of the DAG of a GO term ('signal transduction', GO:0007165) with multiple paths to the GO root, including a different number of nodes.

The *REGULATES* relation states that a process directly affects the manifestation of another process or quality, i.e., when both are present, the former one necessarily regulates the latter one (which may not regulate the former one). For example, *cell cycle checkpoint REGULATES cell cycle* describes that, when a cell cycle checkpoint occurs, it always regulates the cell cycle, but the cell cycle is regulated also by other processes besides cell cycle checkpoints.

The *REGULATES* relation has two sub-relations, *POSITIVELY REGULATES* and *NEGATIVELY REGULATES*, to denote these more specific types of regulation; if A *POSITIVELY* or *NEGATIVELY REGULATES* B, it also *REGULATES* B.

The *OCCURS IN* relation specifies where a biological process or a molecular function takes place. Differently from the other relations, which connect two concepts of the same sub-ontology, it is used for inter-ontology links, mainly to specify relations between a molecular function or a biological process and a cellular component. Such relation can exist only if the occurrent (process or function) always necessarily takes place in the specified location (component), which must exist when the occurrent exist; yet, the existence of the component does not for certain implies that the specific process or function occurs, and in case it may occur only in some instances of that component.

All mentioned relations constitute the *semantic network* of the GO vocabulary; through them, either very general or very precise concepts can be represented.

GO browsers

The Gene Ontology DAG structure describes the intricate underlying biology, which determines the DAG complexity. Thus, the Gene Ontology structure is pretty more complex than a tree. To help inspecting the complex GO DAG structure, several GO browsers have been constructed; the most relevant ones are AmiGO (Carbon *et al.*, 2009) by the Gene Ontology Consortium, QuickGO (Binns *et al.*, 2009) by the European Molecular Biology Library – European Bioinformatics Institute (EMBL-EBI), and GO Browser (Eppig *et al.*, 2017) by the Mouse Genome Informatics (MGI). All of them provide tools for text searching within the GO vocabulary and for displaying graphically the DAG structure of user specified GO terms.

GO Statistics

The Gene Ontology coverage is very ample, with some parts more detailed than others, reflecting the amount of research activities and outcomes reached and increasingly performed in the different biological and biomolecular areas. Since the GO covers the biology of many organisms, the increasing number of studied organisms and the rising knowledge of their biology make continuously growing the already large number of GO terms, i.e., covered concepts, and relations between the expressed concepts.

On June 9th, 2016, the GO included 43,787 terms overall, subdivided in 28,648 biological processes (64.51%), 10,161 molecular functions (22.88%), and 3907 cellular components (8.80%); additionally, there were 1692 obsolete terms (3.81%) not included in the above statistics. In fact, while the GO evolves, previously defined terms which have been refined in their meaning or discarded are kept as obsolete within the ontology, so that to ease compatibility between different GO versions and applications using them. Among the three GO sub-ontologies, the biological process one is the largest and most developed, with terms as much

specific as the *positive regulation of sevenless signaling pathway* (GO:0045874), which is on the seventeenth level of the GO biological process DAG.

Given the increasing size of the GO, more simple subsets of it, named *GOslim* subsets, have been defined to ease its use and interpretability; they provide a broad overview of the ontology content without the details of specific fine grained terms.

Besides a generic GO slim developed by the GO Consortium which is not species specific as the entire GO, available GO slims are created by users based on their needs, and may be specific to species (e.g., plant, yeast, viruses, or a particular model organism) or to particular areas of the GO.

GO Formats and Availability

Being an ontology, the GO is represented with ontology languages and available in file formats able to encode the knowledge about the specific domain, i.e. to describe the nodes and relations, with their multiple features, of the GO DAG. Two file formats are used to this aim: the OBO and the RDF-XML format.

The OBO format uses an ontology representation language and is the text file format used by OBO-Edit, an open source, platform-independent application for viewing and editing ontologies. It attempts to reach the goals of human readability, ease of parsing, extensibility, and minimal redundancy. The OBO 1.2 version is the flat file format used and recommended by the GO Consortium; the concepts that it models represent a subset of the concepts in the Web Ontology Language (OWL) (Knublauch *et al.*, 2006), a family of knowledge representation languages for authoring ontologies, characterized by formal semantics and built upon a W3C XML standard for objects called the Resource Description Framework (RDF) (OWL2, 2009). For the RDF-XML format of the GO, the document type definition (DTD) is also available, which defines the XML document structure and legal building blocks with a list of permissible elements and attributes, allowing consistency checking of the provided GO files.

The latest version of the whole Gene Ontology, as well as its *slim* subsets and mappings to other controlled vocabularies (e.g., InterPro, KEGG, MetaCyc, Pfam, PRINT, ProSite, Reactome, SMART), are publicly available for downloading in the mentioned formats at the GO website and from the GO database archive (see 'Gene Ontology Consortium. Gene Ontology' and 'Gene Ontology database archive' in Relevant Websites Section).

Gene Ontology Annotations

The most relevant use of the GO is in the controlled and computable description of the features of genes and gene products regarding the biological processes, molecular functions and cellular components in which they occur. Such description, known as *annotation*, involves the association of a gene or gene product with a GO concept (term), where usually each gene or gene product is associated with more GO terms, since it has more features, and each GO term (category) is assigned to many genes or gene products, since many genes (gene products) have same features.

Annotations are usually associated with a specific reference, which describes the work or analysis upon which the annotation is based; they can be given in different ways: assigned by experts, i.e., *human curated*, or automatically predicted, i.e., *computationally assigned*, with or without human supervision (curation) (Hennig *et al.*, 2003). Several evidence codes exist and are associated with each annotation to indicate how the annotation to a particular GO term is supported; they are subdivided in two major groups: *automatically* or *manually assigned* evidence codes. The former one includes the IEA (*Inferred from Electronic Annotation*) evidence code, which states that the annotation is based only on automatic computation. The manually assigned (curated) evidence codes are categorized in: *Experimental* (i.e., results exist from a physical characterization that has supported the annotation), *Computational analysis* (i.e., the annotation is based on an *in silico* analysis of the annotated gene or gene product sequence, and/or other data, also according to a varying degree of curatorial input), *Author statement* (i.e., the annotation is funded on a statement made by the author(s) of the associated reference cited), and *Curatorial statement* (i.e., the annotation is based on a curatorial judgment that does not fit in any of the other evidence code classifications). All the elements of each of these categories are as follows:

1. *Experimental*:

EXP: Inferred from Experiment; better to use one of the following more specific experimental codes:

IDA: Inferred from Direct Assay

IPI: Inferred from Physical Interaction

IMP: Inferred from Mutant Phenotype

IGI: Inferred from Genetic Interaction

IEP: Inferred from Expression Pattern

2. *Computational analysis*:

ISS: Inferred from Sequence or structural Similarity

ISO: Inferred from Sequence Orthology

ISA: Inferred from Sequence Alignment

ISM: Inferred from Sequence Model

IGC: Inferred from Genomic Context

IBA: Inferred from Biological aspect of Ancestor

IBD: Inferred from Biological aspect of Descendant
 IKR: Inferred from Key Residues
 IRD: Inferred from Rapid Divergence
 RCA: Inferred from Reviewed Computational Analysis

3. *Author statement:*

TAS: Traceable Author Statement
 NAS: Non-traceable Author Statement

4. *Curatorial statement:*

IC: Inferred by Curator
 ND: No biological Data available; it is usually associated with annotations to GO sub-ontologies route terms, when no data exist to annotate the gene or gene product to that sub-ontology.

A detailed flow chart is provided by the Gene Ontology Consortium to illustrate the steps that lead the curators to decide what evidence code should be assigned to an annotation.

Although related to different types of evidence, evidence codes should not be considered as statements about the quality of the annotation. Each evidence code encompasses multiple different methods that produce annotations, some of higher confidence or greater specificity than other methods, whose application (or result interpretation) can also affect the quality of the annotation. Despite of this, automatically assigned annotations are usually considered to be the ones with the lowest quality, although recently some specific automatic annotation procedures have been demonstrated to be equally reliable than curated ones, which often can be subjective and not highly robust.

When a reference for a GO annotation describes multiple methods, each of which providing evidence for the annotation, then multiple equal annotations with identical GO identifiers and reference identifiers, but different evidence codes, may be made; thus, different evidence codes, although apparently not coherent (e.g., IEA and EXP) can be found associated with the same annotation.

Besides reference and evidence, also an evidence modifier attribute, named *qualifier*, is assigned to GO annotations; it can assume values such as CONTRIBUTES TO, COLOCALIZES WITH, or null, but also NOT or NOT CONTRIBUTES TO, which actually negate the existence of the annotation. Thus, to correctly evaluate a GO annotation, be always careful to consider also the value of its qualifier attribute.

In summary, from a computational point of view, each GO annotation is represented by a record including:

1. Gene (or gene product) ID
2. Gene Ontology ID
3. Reference ID(s) (e.g., PubMed ID(s))
4. Evidence code(s)
5. Evidence modifier (qualifier)

Two examples of GO annotation records are shown in [Fig. 3](#).

True-Path-Rule

Regardless the way in which the annotation is assigned (automatically or manually curated), the assignment must be done to the most specific concept in the ontology that describes the gene or gene product feature that the annotation states; in fact, each annotation to a GO term must satisfy what is known as the *true path rule*: "if a child term of the ontology describes a gene or gene product, then all its parent terms in the ontology must also apply to that gene or gene product" ([Rhee et al., 2008](#)). Thus, thanks to the ontological structure of the GO, this allows automatically inferring the annotation of a gene or gene product also to all the terms that in the ontology are parents of the terms to which the gene or gene product has been annotated to. For example, the biological process *hexose biosynthetic process* has two parents: *monosaccharide biosynthetic process* and *hexose metabolic process*, since *hexose* is a kind of monosaccharide and *biosynthetic process* is a type of metabolic process ([Fig. 4](#)). When a gene or gene product is annotated the *hexose biosynthetic process*, it is automatically annotated also to all its parents terms, and in particular to both *hexose metabolic process* and *monosaccharide biosynthetic process*.

Such automatic unfolding of the ontological annotations allows to store in biological databases only the direct, most specific annotations, thus saving space without losing information power. Furthermore, leveraging on the ontology structure, it allows applying automatic reasoning procedures to predict new unknown gene or gene product features.

Protein ID	GO ID	Evidence code	PubMed ID	Qualifier

Usage in Computational Applications

Gene Ontology annotations are central for many computationally intensive bioinformatics analyses, including *annotation enrichment* analysis (Masseroli *et al.*, 2004; Huang *et al.*, 2007; Masseroli, 2007; Al-Shahrour *et al.*, 2007; Huang *et al.*, 2009) and *semantic similarity* analysis (Pesquita *et al.*, 2009; Schlicker *et al.*, 2010; Jain and Bader, 2010; Tedder *et al.*, 2010; Falda *et al.*, 2012) of genes or proteins, and for interpretation of biomolecular test results, extraction of new information useful to generate and validate biological hypotheses, and for discovering new knowledge.

For reliable GO annotation prediction and prioritization based on an associated likelihood value, several computational methods have been proposed; they include decision trees (King *et al.*, 2003), Bayesian networks (King *et al.*, 2003), k-nearest neighbour (*k*-NN) (Tao *et al.*, 2007) and support vector machine (SVM) classifiers (Minnecci *et al.*, 2013; Mitsakakis *et al.*, 2013), hidden Markov models (HMM) (Mi *et al.*, 2013; Deng and Ali, 2004), and biological network analysis (Warde-Farley *et al.*, 2010; Li *et al.*, 2007). Also simple latent semantic approaches have been suggested to this purpose (Khatri *et al.*, 2005; Done *et al.*, 2010), and then extended with multiple improvements (Chicco and Masseroli, 2015, 2016; Done *et al.*, 2010, 2007; Pinoli *et al.*, 2014b, 2015). More sophisticated latent semantic indexing (LSI) (Dumais *et al.*, 1988) have been proposed to predict new GO annotations based on available ones; they include the probabilistic latent semantic analysis (pLSA) (Hofmann, 1999; Masseroli *et al.*, 2012), also enhanced with weighting schemes (Pinoli *et al.*, 2013), and latent Dirichlet allocation (LDA) (Blei *et al.*, 2003; Bicego *et al.*, 2010; Perina *et al.*, 2010). The LDA technique, associated with Gibbs sampling (Griffiths, 2002; Casella and George, 1992; Porteous *et al.*, 2008), was used to predict gene annotations to GO terms in Pinoli *et al.* (2014a). Lately, other supervised methods were proposed for the prediction of gene GO annotations (Cheng *et al.*, 2014; Stojanova *et al.*, 2013), although with limited predictive accuracy. Overall, such annotation prediction techniques are general and flexible, but provide only limited accuracy, or improve predictions by using a complex model. The latter ones usually are difficult and time consuming to be set up and slow. Recently, a novel representation of the annotation discovery problem

and a random perturbation method of the available annotations were proposed (Domeniconi *et al.*, 2014); taking advantage of supervised algorithms, they allow accurate predictions of novel GO annotations, also regarding the genes of an organism different from the one whose annotations are used for the prediction (Domeniconi *et al.*, 2016).

Gene Ontology Annotation Repositories

The very numerous gene and gene product annotations to Gene Ontology terms are stored in many heterogeneous repositories, including integrative repositories (e.g., GeneCards (Rebhan *et al.*, 1997), and Genomic and Proteomic Knowledge Base (GPKB) (Masseroli *et al.*, 2016)). Above all, the Gene Ontology Annotation (GOA) database (Huntley *et al.*, 2015) is the largest and most comprehensive open-source archive of GO annotations of gene products in multiple species, providing more than 386 million GO annotations to almost 59 million proteins in more than 707,000 taxonomic groups. Managed by the European Bioinformatics Institute (EBI), its aim is to provide electronic and manual annotations of high-quality, ensured by the use of quality control checks, to the proteins from a wide range of species in the UniProt Knowledgebase (Magrane, 2011); furthermore, its use of the standardized GO vocabulary for such annotations promotes a high level of integration of the knowledge in UniProt with other databases. The annotations from GOA are freely available in a variety of annotation file formats, and are also accessible through FTP and Web browser.

Gene Ontology Issues and Solutions

During its development the Gene Ontology faced some problems, mainly due to its growing complexity and the fast increasing knowledge of the domain it describes. The main problem always at risk is that, to be enough comprehensive, several molecular functions, biological processes, and cellular components that are not common to all life forms are described in the GO, despite it should not contain species-specific concepts. Although the current principle is to define in the GO any concept that can apply to more than one type of organisms, as the GO vocabularies expand species-specific terms become problematic; especially, the use of species-specific anatomical terms stays unresolved.

Conflicts in the GO generally manifest when curators from different organism-specific databases add species-specific terms to describe the gene products of their organism. An example of such conflict previously occurred with the introduction in the GO of the biological process term *chitin metabolic process*, which describes cell wall biosynthesis in fungi and cuticle synthesis in insects. Making this concept a sub-process of both *cell wall biosynthesis* and *cuticle synthesis* generated errors, since searches for genes implied in cell wall biosynthesis found also genes concerned with insect cuticle biosynthesis that were annotated to chitin metabolic process. This conflict was solved by creating two types of chitin metabolic processes: one regarding cell wall biosynthesis (i.e., *cell wall chitin metabolic process*), and one related to cuticle synthesis (i.e., *cuticle chitin metabolic process*) (Hill *et al.*, 2002). Yet, as more species-specific terms are progressively included in the GO vocabularies, it is increasingly difficult to keep both the global interspecies relations for which GO struggles, and the accurate terms needed for intra-species gene annotation.

In spite of problems of this and other types (Smith *et al.*, 2003), the Gene Ontology is extremely useful to relate at best many annotations regarding individual biological concepts, but in different species or merely dispersedly described in heterogeneous databases, supporting automatic searches and semantic clustering of different gene annotations.

Conclusion

The GO project is a very important effort regarding three separate aspects: first, the development and maintenance of the GO sub-ontologies; second, the annotation of gene and gene products, which involves making associations between the GO terms and the genes and gene products in collaborating databases; and third, the development of tools that ease the creation, maintenance and use of the GO sub-ontologies.

The use of GO terms by collaborating databases enables the possibility to perform uniform queries across all of them. Moreover, the GO controlled vocabularies are structured in a way that they can be queried at different levels; for instance, users may query GO annotations to find all gene products in the mouse genome that are involved in signal transduction, or zoom in on all receptor tyrosine kinases that have been annotated. Such structure also enables annotators to characterize features of genes or gene products at different granularity levels, depending on the depth of knowledge available about the entity.

Shared standardized vocabularies are an important aspect to unify biological databases, but further work is still needed as knowledge changes, updates hang back, and individual curators evaluate data differently. The GO aims to be a platform where curators can agree on how and why using a specific term, and how to consistently apply it, e.g., to create relationships between gene products.

All these aspects make the GO a very useful instrument both to annotate and describe gene and gene product functions across species, and to connect at best several functional annotations concerning individual biological concepts but related to different species, or simply sparsely stored in heterogeneous databases. Thus, it allows automatically performing controlled searches, functional enrichment analyses, and semantic clustering of diverse gene annotations, which is very useful in many genomic analyses (e.g., high-throughput gene expression) to group genes and gene products to some biological high level concept/term. Besides helping in better interpreting results of such experimental analyses, this ability is fundamental also in characterizing less known genes: if in the same cellular component an uncharacterized gene is co-expressed with well-characterized genes annotated to some GO biological process, one can infer that the “unknown” gene’s product is likely to act in the same process.

Biographical Sketch

Marco Masseroli received the Laurea degree in Electronic Engineering in 1990 from Politecnico di Milano, Italy, and the PhD degree in Biomedical Engineering in 1996, from the Universidad de Granada, Spain. He is associate professor in the Dipartimento di Elettronica, Informazione e Bioingegneria at Politecnico di Milano, and lecturer of Bioinformatics and Biomedical Informatics. He carried out research activity in the application of Information Technology to the medical and biological sciences in several Italian and international research centers. He has also been visiting professor in the Departamento de Anatomía Patológica, Facultad de Medicina at the Universidad de Granada, Spain, and visiting faculty at the Cognitive Science Branch of the National Library of Medicine, National Institute of Health, Bethesda. His research interests are in the area of bioinformatics and biomedical informatics, focused on distributed Internet technologies, biomolecular databases, controlled biomedical terminologies and bio-ontologies to effectively retrieve, manage, analyze, and semantically integrate genomic information with patient clinical and high-throughput genetic data. He is the author of more than 170 scientific articles, which have appeared in international journals, books, and conference proceedings.

Biological and Medical Ontologies: Protein Ontology (PRO)

Davide Chicco, Princess Margaret Cancer Centre, Toronto, ON, Canada

Marco Masseroli, Polytechnic University of Milan, Milan, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

The Protein Ontology (PRO) is a structured controlled vocabulary for protein and protein-related entities, and their corresponding relationships. Developed by Natale and colleagues at Georgetown University Medical Center (Washington, DC, United States), the main goal of PRO is to provide a protein-centric ontology, as an alternative to the multiple gene-centric ontological resources already available in the bioinformatics community (Natale *et al.*, 2007, 2017); an example of a popular ontology is the Gene Ontology (Gene Ontology Consortium, 2013, 2015), which often is exploited by methods related to genes (Pinoli *et al.*, 2015; Chicco and Masseroli, 2015, 2016). One of the goals of the Protein Ontology, in fact, is to fill this gap and provide a complete ontological resource about proteins and proteomics to the scientific community.

PRO integrates the protein information already available in UniProtKB (Boutet *et al.*, 2007) by adding semantic ontological relations and representations of proteins and protein complexes, which are currently missing in other databases. Especially, PRO provides specific information related to what proteins and protein complexes can exhibit as a result of biological processes. Authors fill the PRO resource with information obtained by manual curation from the scientific literature, and by large-scale processing of datasets which supply curated protein and pathway information (largely from UniProtKB). PRO curators use UniProtKB to set the name, the synonyms and the definition of the protein product. Term name and definition follow the conventions used for the human proteins. If no human entry exists, the curators assign the term name from the mouse or *Escherichia coli* (Natale *et al.*, 2011).

In addition to the common protein and protein products, PRO also supplies the representation of specific protein types, which permits precise definition of protein products in pathways, complexes, or in disease modeling. This feature can be exploited in proteomics studies where isoforms and modified forms have to be clearly identified, and for biological network representation where event series can be related to specific protein modifications.

We organize this article as follows. After the Introduction section, first we mention the development and statistics of the PRO ontology (see Section Development and Statistics), describe its content and structure (see Section Content and Structure), and the PRO tools and annotations (see Section Tools and Annotations). We then explain a use case related to PRO (see Section Use Case), and mention some projects which took advantage of PRO (see Section Related Applications). We finally list some recent enhancements of PRO (see Section Recent Enhancements) and draw some conclusions (see Section Conclusions).

Development and Statistics

Natale and colleagues first introduced the Protein Ontology in 2006 (Natale *et al.*, 2007), and then released new versions in 2011 (Natale *et al.*, 2011), in 2014 (Natale *et al.*, 2014) and in 2017 (Natale *et al.*, 2017). Bult *et al.* (2011) described a representation of protein complexes in PRO in 2011, and Arighi *et al.* (2011) published a tutorial on PRO in the same year.

The number of PRO protein entities has always augmented, since its first release in 2007. At the time of writing this article, in the current PRO version 52.0, its stats Web page lists 213,457 total protein terms, 1674 annotations derived from curated papers, 4419 annotations derived from Gene Ontology (GO) terms, and 130,442 protein sequences derived from UniProt.

Content and Structure

Authors designed the Protein Ontology following the Open Biological and Biomedical Ontology (OBO) Foundry principles (Smith *et al.*, 2007). Thanks to some of these principles, it has an open copyright license that allows anyone to use and reuse it; it is written in common format and syntax, whose rules are respected in each aspect and data of the ontology; each data element has an associated unique Uniform Resource Identifier (URI); it has a large documentation available. In addition, each Protein Ontology entry has a specific ID code, and an associated Web page and URL address.

The ontology is organized in five meta-classes, in hierarchical order (Arighi, 2011):

- *Family*: representing classes of proteins derived from a specific set of common ancestor genes. An example of this class entity is PRO:000000676. This protein entity is “A protein with amino- and carboxyl-terminal intra-cellular domains separated by a domain (common with other ion channels) containing six transmembrane helices (S1–S6) in which the last two helices (S5 and S6) flank a loop, called the pore loop, which determines ion selectivity”;

- *Gene*: representing proteins as direct products of a specific gene. An example of this class entity is PR:000000705. This entity is: “A potassium/sodium hyperpolarization-activated cyclic nucleotide-gated channel protein that is a translation product of the human HCN1 gene or a 1:1 ortholog thereof”;
- *Sequence*: representing protein products with a distinct sequence on initial translation. An example of this class entity is PRO:000003420, which is “A PC4 and SFRS1-interacting protein isoform 1 that has not been subjected to any co- or post-translational residue modification or peptide bond cleavage” corresponding to isoform 1 (p75) derived from gene LEDG.
- *Modification*: representing protein products evolved from a single messenger RNA (mRNA) species that differ because of some change that occurs after the initiation of translation. An example of this class entity is PR:000003423, which is “A PC4 and SFRS1-interacting protein isoform 2 that has not been subjected to any co- or post-translational residue modification or peptide bond cleavage”;
- *Complex*: representing protein complexes with a specific defined subunit composition. An example of this class entity is PR:000035566, that is “A protein complex that is composed of BUB1 and BUB3. This complex is involved in the inhibition of anaphase-promoting complex or cyclosome (APC/C) when spindle-assembly checkpoint is activated”.

In PRO, two different types of relations can link two protein entities (Natale *et al.*, 2011):

- *is_a* indicates the subtype relation between child and parent term;
- *derives_from* indicates the relation between a proteolytic cleavage product and its fully-formed precursor.

PRO takes advantage of the popular sequence database UniProtKB (Boutet *et al.*, 2007), and relates with the biological ontology Gene Ontology. In PRO, the organism-specific clusters of proteins encoded by a specific gene link to protein products documented in UniProtKB. The Protein Ontology both uses UniProtKB as a source of protein entities, and complements this database by supplying formal definition of protein products, together with their relationships in the ontological context. PRO links also to the Gene Ontology, regarding its complex meta-class. The representations of organism-specific protein complexes in PRO are sub-classes of the organism-independent protein complex terms in the Cellular Component (CC) GO sub-ontology: multiple GO Cellular Component terms are parent terms for PRO complex terms.

The Protein Ontology furnishes protein data related not only to human genes, but also references to other organisms such as mouse, *Escherichia coli*, *Saccharomyces cerevisiae*, and *Arabidopsis thaliana*. In the last years, the Protein Ontology curators also added the mappings of the PRO entities to external databases such as UniProtKB (Boutet *et al.*, 2007), Reactome (Croft *et al.*, 2014), EcoCyc (Keseler *et al.*, 2005), plus gene mappings for Mouse Genome Database (Bult *et al.*, 2008), HUGO Gene Nomenclature Committee (HGNC) (Povey *et al.*, 2001), EcoGene (Rudd, 2000), and the Saccharomyces Genome Database (Issel-Tarver *et al.*, 2002). Multiple PRO entities, in fact, are associated with entities of the aforementioned resources through identity relationships. The same proteomics concept can be present in both PRO and Reactome, with different ID's, linked through a PRO external relation.

We report an example of Protein Ontology entity in Fig. 1.

Tools and Annotations

The Protein Ontology can be accessed through the internet, can be explored through Cytoscape (Smoot *et al.*, 2011), or can be downloaded into plain files. PRO also provides a set of annotations related to protein and protein entities. PRO curators, in fact, analyze the scientific literature to find references to proteins and protein complexes in order to collect protein annotations and their associated evidence. PRO includes annotations to attribute (such as protein function, localization, process and involvement in disease) in the PRO association file (PAF), available for download.

PRO expresses each annotation as an association between a protein entity and a term from controlled vocabularies (such as the Gene Ontology and others), and their corresponding relationship (Natale *et al.*, 2011). In the aforementioned example (Fig. 1), the annotations of the protein *smad2 isoform 1 phosphorylated 1* are listed by PRO in the lower part of the record. The example shows that this isoform is linked to the “transcription coactivator activity” (GO:0003713), which is a molecular function GO term, through a “has_function” relation.

In addition, the Protein Ontology allows the users to submit their own protein products and protein annotations, through a tool called Rapid Annotation interfaCE for PRotein Ontology (RACE PRO). On its online Web page, anyone can suggest a protein-associated entity by supplying a scientific paper related to it. This way, inexperienced users with no specific knowledge of proteomics can contribute to PRO as well. After the receiving of a request, the PRO editor checks the information and, if the request is accepted, converts it into the proper PRO format. Finally, he/she sends it back to the original submitter for confirmation and, after his/her final approval, the editor adds it to the Protein Ontology.

PRO is also accessible through BioPortal, an online resource of biomedical ontologies, provided by the National Center for Biomedical Ontology (Musen *et al.*, 2012).

Use Case

An interesting and complete use case for the usage of the Protein Ontology has been described by Ross *et al.* (2013), which took advantage of PRO to analyze a biological process called *spindle checkpoint*. The spindle checkpoint is a highly conserved

Protein Ontology Report - hSMAD2/iso:1/Phos:1

Fig. 1 Example of a Protein Ontology entry in the PRO browser: PR:000025934, corresponding to “A smad2 isoform 1 phosphorylated 1 in human. This form is phosphorylated in the two last Ser of the C-terminal SSxS motif”. Its category is organism-modification. This isoform is also present in Reactome with the listed ID code R-HSA-177099 and the corresponding hyper-link. The browser lists the Gene Ontology terms associated to this protein entity in the lower part of the screenshot, including the hyper-links for the Gene Ontology terms, and the references to the PubMed scientific papers describing the relation between the GO term and the protein entity (e.g., PMID:9311995).

biological process strongly related to protein modification and protein complex formation. The authors took advantage of the Protein Ontology and of other bioinformatics tools to explore the cross-species conservation of spindle checkpoint proteins, including phosphorylated forms and complexes. The authors also studied the impact of phosphorylation on spindle checkpoint function, and the interactions of spindle checkpoint proteins with the site of checkpoint activation (kinetochore) (Ross *et al.*, 2013).

Authors started their analysis with a PubMed literature search of the keywords *BubR1* and *Bub1* (which are the names or synonyms of the checkpoint protein *BUB1*), and *Mad3*, which is the closest yeast relative of *BUB1B*. The authors collect all the information related to the proteins for which there were experimental data available, from PubMed and other datasets, and inputted them into the previously introduced RACE-PRO. All the information submitted by the authors to RACE-PRO were checked by the PRO editor and converted into PRO terms through a semi-automated process which also establishes the hierarchy of each term in the ontology. Once these terms were available on PRO, the authors browsed them through the PRO website and its graphical display tools, such as the Cytoscape view (Smoot *et al.*, 2011).

Through the Cytoscape view, the authors were able to identify the kinetochore protein-protein interaction (PPI) network for the *spindle checkpoint*. Using a script, the authors extracted the name, definition, category, and label of the PRO terms retrieved and of the kinase-substrate relationships. The authors extracted the protein binding related annotations (identified by the GO evidence code “inferred from physical interaction” or IPI) from the PAF file provided by PRO. Their script then generated two tab-delimited text files, which are importable into Cytoscape: a network file containing each pair of interacting proteins, its interaction type, and the corresponding evidence and a PRO entry information file containing PRO ID and entity description (Ross *et al.*, 2013). By analyzing this list of PRO terms, authors were able to infer interesting relationships and new terms regarding the input spindle checkpoint proteins.

Related Applications

Many scientific projects have used the Protein Ontology in the past; here we list the main applications available in literature.

Ross *et al.* (2013) described a case study in which they took advantage of PRO to analyze a biological process called *spindle checkpoint*. We explore more in depth this case study in Section Use Case. Rocca-Serra *et al.* (2011), on the other hand, took advantage of PRO to associate chemical and enzymatic probes to protein products. In this project, the authors propose a standard method for reporting the results of mapping experiments for the characterization of single nucleotide resolution nucleic acid structure. One of the steps of this method is the association of protein entity information to chemical enzymes: authors perform this operation by querying the Protein Ontology.

The Protein Ontology can also be used as a reference support for text mining. Funk *et al.* (2014) in fact, exploited it to test dictionary-based systems for biomedical concept recognition. Maiorana (2012) used the Protein Ontology to retrieve protein information related to Huntington Disease. A typical usage of the Protein Ontology was shown by Li *et al.* (2016) recently. The authors of this article, studying the types of human dental follicle cells (DFCs) and periodontal ligament cells (PDLs), took advantage of PRO and identified 2138 proteins related to those cell types. They then identified 39 of these proteins as consistently differentially expressed between DFCs and PDLs. To complete their study, the authors analyzed these 39 proteins by querying the Protein Ontology, inferring additional information about them and their products.

Recent Enhancements

The Protein Ontology curators released a new version of PRO in October 2016, featuring several enhancements (Natale *et al.*, 2017). One of the goals of the latest and current version of PRO at the time of writing this article, in fact, is to provide a standard representation of proteoforms by employing UniProtKB as a sequence reference, and Protein Structure Initiative Modification Ontology (PSI-MOD) as a post-translational modification reference. This feature is able to let users retrieve information about proteoforms more easily across several resources.

Another enhancement regards scalability and text mining. Authors included iPTMnet, a tool for the integration of post-translational modification (PTM) information from curated databases, and the results of broad text mining of PubMed abstracts performed with RLIMS-P (Torii *et al.*, 2015).

Also the Histone database (Khare *et al.*, 2012), which provides a collection of human histone modifications, has been included in the last version of PRO. The PRO curators downloaded the Histone data and converted them by a script to generate their PRO instances. In the first integration, authors produced 468 Histone evidenced PRO terms.

Another novelty of the latest version of PRO regards the dynamic generation of terms. Up to the previous PRO version, data inclusion requests were filled fully manually by the PRO curators. To quicken this process, the PRO authors have added the capability for some specific terms (gene-level and sequence-level terms) to be generated dynamically, from UniProtKB. As the authors explain (Natale *et al.*, 2017), UniProtKB-derived terms can be defined as “a protein that is a translation product of gene X in organism Y”. Since these items of information are already available in the UniProtKB database for that entry, PRO takes advantage of UniProtKB's Web service and dynamically adds the entry as a PRO term in its database.

While other novelties refer to the Web interface of PRO, it is worth mentioning that the last version of PRO also links to SPARQL (Quilitz and Leser, 2008). The PRO curators produced a resource description framework (RDF) linked data repository that contains information about the PRO term file and the associated PRO annotation file. Upon this RDF, the authors developed a SPARQL endpoint server for PRO through OpenLink Virtuoso (Erling and Mikhailov, 2009). This feature allows the PRO users to query against PRO data following the W3C SPARQL specification, and therefore retrieve terms, subclasses, and functional annotations from PRO, with or without inference. The PRO SPARQL endpoint is publicly accessible over the Internet.

Conclusions

The Protein Ontology curators started this project with an ambitious goal: create a new ontological resource for proteomics, which might have been as useful and handy as the popular Gene Ontology for all the scientific community. Even if PRO contains multiple proteomics entities and is linked to multiple external resources, it is still not as spread as GO.

The PRO curators are currently working on developing new collaborations with external scientists for future PRO extensions and integrations. One of the future integrations of PRO will be with the Immunology and Data Analysis Portal (ImmPort) (Bhattacharya *et al.*, 2014), an immunology data resource whose integration will make PRO able to associate protein entities to antibodies, among others. The curators are also working on linking together PRO and the Proteoform Repository, a new databank for proteoforms developed at the Northwestern University (Chicago, Illinois, United States). With this new extension, PRO will enable users to analyze conserved modifications among *Homo sapiens* and other organisms, to analyze the associations between proteins and function information contained in Proteoform Repository, and to analyze relationships between proteoforms.

With these new integrations and a better communication campaign, we believe that the Protein Ontology can become the reference proteomics ontology for the scientific community.

Biographical Sketch

Davide Chicco obtained his Bachelor of Science and Master of Science degrees in computer science at Università di Genova (Genoa, Italy), respectively in 2007 and 2010. He then started the PhD program in computer engineering at Politecnico di Milano university (Milan, Italy), where he graduated in Spring 2014. He also spent a semester as visiting doctoral scholar at University of California Irvine (Irvine, California, United States). Since September 2014, he has been a post-doctoral researcher at the Princess Margaret Cancer Center and guest at University of Toronto (Toronto, Ontario, Canada). His research topics focus upon mainly machine learning algorithms applied to bioinformatics.

Marco Masseroli received the Laurea degree in electronic engineering in 1990 from Politecnico di Milano, Italy, and the PhD degree in biomedical engineering in 1996, from the Universidad de Granada (Granada, Spain). He is associate professor and lecturer of bioinformatics and biomedical informatics in the Dipartimento di Elettronica, Informazione e Bioingegneria at Politecnico di Milano university (Milan, Italy). He carried out research activity in the application of Information Technology to the medical and biological sciences in several Italian and international research centers. He has also been visiting professor in the Departamento de Anatomía Patológica, Facultad de Medicina at the Universidad de Granada (Granada, Spain), and visiting faculty at the Cognitive Science Branch of the National Library of Medicine, National Institute of Health (Bethesda, Maryland, United States). His research interests are in the area of bioinformatics and biomedical informatics, focused on distributed Internet technologies, biomolecular databases, controlled biomedical terminologies and bio-ontologies to effectively retrieve, manage, analyze, and semantically integrate genomic information with patient clinical and high-throughput genetic data. He is the author of more than 170 scientific articles, which have appeared in international journals, books, and conference proceedings.

Biological and Medical Ontologies: Disease Ontology (DO)

Anna Bernasconi and Marco Masseroli, Politecnico di Milano, Milan, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

The nomenclature of human diseases has traditionally been defined according to the name of the scientist who discovered the disease (e.g., *Larsen Syndrome*), or where the disease was first revealed (e.g., *Japanese spotted fever*), or the animal in which the disease was first identified (e.g., *Cowpox*). Across the multitude of different resources, this tradition highlights a strong need for a standardized way of representing human diseases, in order to boost interoperability between resources, to connect gene variation to phenotype targets, and to support the use of computational tools that can use disease information to perform important data analysis and integration.

The Disease Ontology (DO) provides a single unifying representation of biomedical data that are associated with human diseases. It contains standardized disease descriptors that are both human- and computer-readable. DO terms are well-defined and linked (with frequent updates) to established terminologies that contain disease and disease-related concepts, such as Systematized Nomenclature of Medicine Clinical Terms (SNOMED-CT) (Donnelly, 2006), International Classification of Diseases (ICD-9 and ICD-10 versions) (see 'ICD, World Health Organization' in Relevant Websites section), Medical Subject Headings (MeSH) (Lipscomb, 2000), and Unified Medical Language System (UMLS) (Bodenreider, 2004).

The disease descriptors of the DO have been created by combining project specific genetic/genomic disease terms with resources deriving from the study of human disease through the analysis of model organisms. The actual corpus of DO diseases includes genetic, environmental, and infectious diseases of interest both for clinical research and medicine. It encompasses multiple mammalian genomic resources enabling inference between different datasets that use the included standard terminologies to describe disease.

The activities that mostly benefit from semantically consistent disease annotations (like the ones made possible by the DO) include diagnostic evaluation, treatment and clinical or experimental data comparisons over time and between different studies. Before the DO was developed, many vocabularies and ontologies included disease and disease-related concepts, but none of these was structured around the concept of disease.

The DO has become an established reference point for any reasoning that involves finding relationships between disease concepts, genes contributing to disease and the plethora of symptoms, findings, and signs associated with disease. Its authority is by now widely recognized by the research community, since it encapsulates a comprehensive theory of disease.

The Disease Ontology was first developed by the Center for Genetic Medicine of Northwestern University (Chicago, Illinois, United States) in 2003. The initial drive was the data curation need of the NUGene Project at the Center for Genetic Medicine. The first releases (in 2003 and 2004) referred to the International Classification of Diseases in its 9th version (ICD-9) as their foundational vocabulary, reorganizing its terms by process, affected system, and cause (including metabolic and genetic disorders, as well as infectious diseases). Since ICD-9 is a set of billing codes rather than a proper disease terminology, it features highly variable granularity of terms; thus, the DO development team soon realized that it was not the right choice as basis for the DO. A re-visitation of the initial choices led to building a new version of the DO based on disease concepts in UMLS, taking advantage of them to create mappings to SNOMED-CT and ICD-9.

The version of the ontology described in Schriml *et al.* (2012) had a strong impact on the development of the following biomedical resources, as documented by the high number of references to the paper in the biology and bioinformatics literature. The new DO followed the Open Biomedical Ontology (OBO) and OBO Foundry principles. The DO became open source and maintained in a well-defined exchange format (OBO and OWL), with clearly specified content, definitions, and relations (i.e., *is_a* and *part_of*) that are formatted according to the OBO Relations Ontology standards.

Between 2012 and 2015 the content of the DO has been revised 192 times with the addition of many terms. In the version of the ontology described in Kibbe *et al.* (2015) the content has grown notably, the data structure has undergone improvements, the community-based organization has switched from OBO to Web Ontology Language (OWL) based curation of the DO.

Advances have been mainly dedicated to data content: representing common and rare diseases (thanks to the collaboration with OMIM (Hamosh *et al.*, 2005), Orphanet (Rath *et al.*, 2012), and the National Organization for Rare Disorders (see 'NORD' in Relevant Websites section)), assessing genomic variants of cancers, defining human disease according to model organism databases, homogenizing unequal disease representations, and connecting disease and phenotype information.

The curatorial efforts have targeted in particular rare genetic diseases, cardiovascular diseases, neurodegenerative diseases, inherited metabolic disorders, diseases related to intellectual disabilities and cancer. Still at the time of writing, the research community is always at the forefront in guiding the curation of the DO by requesting the inclusion of new terms and the revision of groups of terms utilized in the research.

Mission and scope of the DO project are clearly stated on its main Web page, aiming at gathering an always greater plurality of users, who participate to the DO collaborative, community-driven, development. It also features a Wiki page that provides an overview of the project, interesting links and contacts. In August 2006 it was submitted for inclusion and review to the OBO Foundry, and it is now an OBO Foundry ontology.

The DO has been funded by the National Center for Research Resources (NCRR) of the National Institutes of Health (NIH). The comprehensive project is hosted at the Institute for Genome Sciences at the University of Maryland School of Medicine (Baltimore, Maryland, United States).

In May 2017, at the time of writing this article, the BioPortal (Noy *et al.*, 2009) website listed 6 projects using this ontology: Biomedical Semantic QA (Balikas *et al.*, 2015), DisGeNET-RDF (Piñero *et al.*, 2017), Epidemic Marketplace (Silva *et al.*, 2010), FlyBase (Gramates *et al.*, 2017), Gemma (Zoubarev *et al.*, 2012), and Neurocarta (Portales-Casamar *et al.*, 2013).

After this introduction, this article first describes the DO with focus on its scope, structure, terms, and relations. The following sections include: a quantitative perspective on the coverage and mappings provided by the ontology in its different releases, an overview of the technological aspects regarding its access, Web browser and API, a list of notable applications that employ the ontology in their work, and information about the ongoing changes and expected future developments, along with a use case scenario describing a simple user activity.

The Disease Ontology

The DO is intended as a single relational structure to organize the classification of disease, able to unify the representation of disease among various terminologies. It allows inference and reasoning using the disease concepts and their relationships, and it is optimized to facilitate disease annotations of other sources.

Scope of the DO

The Disease Ontology is based on the definition of disease: “a disposition to undergo pathological processes that exists in an organism because of one or more disorders in that organism”. This definition was given by the Ontology of General Medical Science (OGMS), as documented in Scheuermann *et al.* (2009).

The DO, like the model Gene Ontology, arranges *terms* (also referred to as *classes*, which is used as a synonym in this article) in a Directed Acyclic Graph (DAG) in such a way that traversing it from the root toward the leaves corresponds to progressively moving toward more specific terms. Its organization ensures that the true-path rule (Gene Ontology Consortium, T.G.O., 2001) always holds.

The DO includes only concepts that strictly represent diseases. Note that concepts related to the progression of disease (e.g., early, late, metastasis, stages) and manifestations of disease (e.g., transient, acute, chronic) are not included as part of a disease definition. Moreover, terms describing the combination of two disease concepts (e.g., *glaucoma associated with pupillary block*) are not included, but rather the two diseases are represented through two separate terms (i.e., *glaucoma* and *pupillary block*).

Structure of the DO

The DO is logically divided by major types of disease to enable a guided exploration of the ontology (e.g., using its Web browser).

The DO is organized according to a clinical perspective of disease etiology (i.e., disease origins or causes) and location. Its graph-structure presents terms linked by hierarchical and computable relationships (e.g., *brain sarcoma* is_a *brain cancer*, and *brain cancer* is_a *central nervous system cancer*). The terms are divided into eight high-level bins to represent cellular proliferation (i.e., *benign neoplasm*, *cancer*, or *pre-malignant neoplasm*), mental health (e.g., *cognitive disorder*), anatomical entities (e.g., *endocrine*, *cardiovascular*, or *gastrointestinal disease*), infectious agents (i.e., *bacterial*, *fungal*, *parasitic*, or *viral infectious disease*), metabolism diseases (i.e., *acquired* or *inherited metabolic disease*), genetic diseases (e.g., *chromosomal disease*), medical disorders (e.g., *visceral heterotaxy*), and syndromes (e.g., *chronic fatigue syndrome*).

In the ontology, all terms are anchored by stable and traceable identifiers (DOIDs) that consist of the prefix DOID: followed by number. As an example, *Parkinson's disease* has the identifier DOID:14330.

Example term

A relevant advantage of expressing information on the phenotype in form of an ontology is that search procedures can exploit the semantic relationships between the used ontology terms as the example below shows. The Disease Ontology entry for *Lateral sclerosis* in OBO format is given in Table 1, featuring its identification number (DOID) within the ontology, name, textual definition, external links to other classification schemes, subsets it belongs in (i.e., subsets of biomedical ontologies, called *slims*, created to provide customized high-level views (Davis *et al.*, 2010)), synonyms, and relations it participates in.

Relations in the DO

Textual definitions of the ontology terms include *relations* (also called *properties*), taken from a defined set of possibilities. The DO features a total of 15 properties (as defined in the OWL version of the ontology).

Table 2 shows the properties that are used to annotate concepts in the OWL version of the ontology that is released at the time of writing this article. Note that the column *Relation* reports the name of the ObjectProperty as it is used in the OWL version file of the ontology. The column *Use* indicates the description of the AnnotatedTarget field in the OWL file data type description, and the column *Example* shows a sample value of the AnnotatedTarget field of one ontology entry.

Table 1 Example of DO term: Lateral sclerosis

<i>Id</i>	<i>DOID:230</i>
Name	Lateral sclerosis
Definition	A motor neuron disease characterized by painless but progressive weakness and stiffness of the muscles of the legs. Available at: http://en.wikipedia.org/wiki/Primary_lateral_sclerosis/ , https://rarediseases.org/rare-diseases/primary-lateral-sclerosis/
Xrefs	ICD10CM: G12.29 ICD9CM:335.24 MESH: D016472 OMIM:611637 ORDO:35689 SNOMEDCT_US_2016_03_01:81211007 UMLS_CUI:C0154682
Subsets	DO_rare_slim
Synonyms	Adult-onset primary lateral sclerosis [EXACT] Primary lateral sclerosis [EXACT] [ICD9CM_2006:335.24]
Relationships	is_a DOID:231 motor neuron disease

Table 2 List of relations in the disease ontology

<i>Relation</i>	<i>Use</i>	<i>Example</i>
complicated_by		DOID:6905, A herpes zoster that is <i>complicated_by</i> AIDS.
composed_of	Component parts of anatomy of tissue made up of certain cells or other body area/system or tissue types.	DOID:2661, A sweat gland neoplasm that is <i>composed_of</i> outgrowths of myoepithelial cells from a sweat gland.
derives_from	Type of tissue or cell/the source of the material.	DOID:2671, A carcinoma that <i>derives_from</i> transitional epithelial cells.
has_material_basis_in		DOID:2762, A bone cancer that <i>has_material_basis_in</i> abnormally proliferating cells <i>derives_from</i> epithelial cells.
has_symptom	Symptom(s) associated with disease.	DOID:3049, A vasculitis that is systemic vasculitis realized as blood vessel inflammation and <i>has_symptom</i> asthma along with hay fever, rash and gastrointestinal bleeding.
is_a		DOID:1311, A renal infectious disease <i>is_a</i> Human immunodeficiency virus infectious disease [...].
located_in	Anatomical location.	DOID:1324, A respiratory system cancer that is <i>located_in</i> the lung.
results_in	Development process/cause and effect/disease progress, process.	DOID:0050068, A bubonic plague that <i>results_in</i> a benign form of bubonic plague [...].
results_in_formation_of	Formation of structure, cancer, etc./cause and effect.	DOID:0050096, A dermatophytosis that [...] <i>results_in_formation_of</i> noninflammatory superficial perfollicular pustules.
transmitted_by	Pathogen is transmitted.	DOID:0050082, A viral infectious disease that [...] is <i>transmitted_by</i> blood transfusion.

Additional relations, defined in the OWL file as ObjectProperty are *inheres_in*, *occurs_with*, *part_of*, *realized_by*, and *realized_by_suppression_with*. These are not used in any textual definition yet.

An example of a definition that combines multiple relations is the textual definition of the term DOID:13021, *AIDS-related cryptococcosis*: “A cryptococcosis that *is_a* disease associated with AIDS *has_material_basis_in* *Cryptococcus neoformans* which *results_in* a systemic infection in individuals with HIV.”

Quantitative Aspects

In the version of the DO documented in the 2012 Nucleic Acid Research paper (Schriml *et al.*, 2012), the ontology represented a knowledge base of 8043 human diseases (divided into inherited, developmental and acquired) (DO version 3, revision 2510). The same version featured textual definitions for 22% of the DO terms. Additionally, 932 logical definitions were provided (in the HumanDO_xp.obo file) to express the annotation of disease attributes (e.g., symptom, phenotype, anatomical or cellular location, and pathogenic agent) linking the DO terms to orthogonal ontologies (such as the Foundational Model of Anatomy (FMA) (Rosse and Mejino, 2003), Human Phenotype Ontology (HPO) (Köhler *et al.*, 2016), NCBI organismal classification

vocabulary (NCBI Resource Coordinators, 2013), PATO (Gkoutos *et al.*, 2005), and Gene Ontology (Ashburner *et al.*, 2000) among others).

The version of the DO documented in the 2015 Nucleic Acid Research paper (Kibbe *et al.*, 2015) resulted after 192 revisions of the ontology OBO version file. This release was marked as the revision 2702 (6 October 2014), and it featured 8803 classes, i.e., diseases (which corresponded to an increment of 760 with respect to the previous NAR publication version), 2384 of which to be considered obsolete. This newer version featured textual definitions for the 32% of DO terms (2087 out of the 6419 non-obsolete ones).

At the time of writing this article, in May 2017, according to the most updated version, the Disease Ontology features 10,831 concepts in total. According to the BioPortal profiling, these are arranged in 12 levels of depth. The maximum number of children for a single class is 107. On average, a class has around four children. There exist 554 classes with only one child, which represents a specialization nomenclature for that class. There are 34 classes that have more than 25 children classes. 7206 classes have no definition.

Mapping with Other Ontologies

The DO addresses the complexity of disease nomenclature by semantically integrating disease and medical vocabularies through extensive cross-mapping of MeSH, ICD-9, ICD-10, NCI's thesaurus (Sioutos *et al.*, 2007), and SNOMED-CT. All terms are extracted from the Unified Medical Language System (UMLS) based on UMLS Concept Unique Identifiers (CUIs). Note that the DO updates vocabulary mappings twice yearly through the extraction of term CUIs from the UMLS vocabulary mapping file. Additionally, the DO also includes concepts extracted directly from Orphanet, OMIM, and the Experimental Factor Ontology (EFO) (Malone *et al.*, 2010). These mappings provide a rich resource for semantically connecting phenotypic, gene and genetic information related to human disease.

Through the mapping process, 91% (7845 out of 8588) of DO terms were mapped to UMLS CUIs (DO version 3, revision 2490, August 2011), a result that represented a 7% reduction of UMLS mappings since the May 2010 DO-UMLS mapping. This reflected DO's increased utilization of logical definitions to define complex disease relationships, which had decreased the number of unique DOIDs. Indeed, note that logical definitions allow to define the relationship between a type of organ disease, such as a *gallbladder adenocarcinoma*, and a cell type, such as the *adenoma*, as a type of adenoma. Moreover, they allow to define the anatomical location of a disease (e.g., *gallbladder adenocarcinoma* is located_in the *gallbladder*).

In the DO version documented in Schriml *et al.* (2012), multiple is_a relationships, which had been inherited from the UMLS vocabularies, were greatly reduced.

As a study on cross-comparison performed in Kibbe *et al.* (2015) shows, the DO provides the largest number of unique cross-references (35,895) among seven different disease vocabularies. This number represents around the 64% of the total unique cross-references in each disease vocabulary, with more than four cross-references on average for each term. Such result highlights the DO's role as a resource rich in cross-references and useful as a disease-centric scaffold for data.

As reported by the interoperability study shown in BioPortal website (Salvadores *et al.*, 2013), as of 15 September 2014, BioPortal mapped the DO classes to classes within 128 other biomedical ontologies also included in its repository. At the time of the writing of this article, DO has increased these mappings of 43 units (for a total of 171 ontologies).

Notable overlapping is observed with OMIM, where 3602 concepts of DO coexist, SNOMED-CT (3062 overlapping terms), and Human Phenotype Ontology (2154 overlapping terms). The highest number of overlapping classes is reached in Medical Dictionary for Regulatory Activities (8996) (Brown *et al.*, 1999), National Cancer Institute Thesaurus (8986), and Cigarette Smoke Exposure Ontology (8234) (Younesi *et al.*, 2014). Conversely, the International Classification of Diseases (Version 10) features 2130 overlapping terms with the DO.

Technological Details

Access Modes

The Disease Ontology can be downloaded in alternative ways. The OBO Foundry portal hosts a version which is updated daily. A GitHub repository and a Sourceforge website host synchronized versions of the ontology. Both OBO and OWL formats are available.

On the Disease Ontology webpage, several services are available for users. These include a Term Tracker to submit new terms, definitions or suggestions, a Wiki documentation, the link to the Twitter, LinkedIn, Facebook, Google+ pages, and other resources.

A curation style guide provides documentation on defining new terms and standardizing their format, as well as on creating definitions, IDs for external references, and URLs for provenance of term definition sources.

Disease ontology files are available under the Creative Commons Public Domain Dedication CC0 1.0 Universal license, which allows copying, modification and distribution of the Disease Ontology content, without asking for permission. They are available in three formats: the OBO formatted Disease Ontology (HumanDO.obo), the Disease Ontology file without cross-references (HumanDO_no_xrefs.obo), and an enhanced Disease Ontology file containing logical definitions to other OBO Foundry ontologies (HumanDO_xp.obo).

The Disease Ontology can also be explored using the Web browsers in EBI's Ontology Lookup Service and NCBO's BioPortal (this also exhibits a service to query the ontology using the SPARQL standard, see 'BioPortal SPARQL queries' in Relevant Websites section).

The DO Web Browser

The DO browser is a Web 2.0 application designed with Semantic Web technologies to allow an easy exploration of the DO, through both a full-text search and a visualization function.

The database

The ontology metadata are stored in Neo4j (Webber, 2012), a NoSQL graph database server. Neo4j is an embedded, disk-based, transactional Java persistence engine that stores data structured in graphs.

Each DO term is modelled as a Neo4j graph node containing the following properties: Name, DOID, Definition, Synonym(s), Alternate ID(s), Subset(s), Cross-Reference(s) and Relationships. The relationships between terms of the ontology are represented as edges of the graph (with a relationship type).

Note that representing graph structures that include multiple relationships is very easy in a graph-based persistence engine such as Neo4j. While a relational database would store ontology terms in one table with a one-to-many connection to another table containing relationships, a graph database stores terms as nodes that are connected to each other by edges (relationships). This paradigm provides several robust mechanisms to retrieve data very fast. Built into Neo4j there are optimized functions for retrieving individual nodes, but also the path between two terms (all paths, the shortest one, user-defined variants), a quite useful feature to make ontology visualization more meaningful.

The rich RESTful API of Neo4j enables advanced users familiar with the Neo4j RESTful API to request data from the Disease Ontology database in a programmatic way and facilitates integration into external projects. The DO browser exploits them to retrieve nodes and their properties (i.e., relationships) via HTTP service calls.

The visualization

The DO browser presents the ontology tree, query results, and terms metadata in a unified point of visualization, where multiple tabs can be selected on a single web page. This page is divided into three areas: the search panel, the navigation panel and the content panel (Fig. 1).

The navigation panel allows visualizing the ontology in a hierarchical structure, i.e., a navigation tree that permits double clicks to expand classes in order to see the related subclasses, and to move from relation to relation.

The search panel supports a basic search (allowing query terms that correspond to DOIDs, names, synonyms, external references, or free text that can be found in definition fields), or an advanced kind of search; this additional feature allows creating targeted and complex queries. Boolean operators are featured to compose conjunctive/disjunctive queries, where the type of data (such as Name, Synonym, DOID, etc.) can be set.

The search for terms is based on concept mapping, with a Lucene (see 'Apache Lucene' in Relevant Websites section) scoring index of matches based on word matches. The Lucene scoring index weighs matches in order (highest to lowest): name, synonym, definition, subset, and ID.

The submitted search returns an output which is visualized in the content panel, in pages of 30 terms from which it is possible to navigate forward or backward. By clicking on a DOID entry belonging to a query result, or from the navigation tree, it is possible to visualize its detailed description (metadata).

A graph interactive view of a selected term can be opened by choosing the functionality *Visualize* from the metadata panel. This creates a new tab that hosts an interactive canvas upon which the target term and any of its children or parents are rendered and can be explored. A red node keeps memory of the first target node of the visualization. Its child or parent nodes have a green label and can be expanded by double clicking on them. Leaf nodes are marked through a grey label and cannot be further expanded. Nodes with more than 5 relatives are compacted into a yellow circle node indicating how many nodes are not being shown. The user can explore these compacted branches by clicking on the yellow circle and selecting to add to the graph only certain children/parents (or all of them). When this choice is made, they are shown in the visualization canvas. The user must be aware that requesting a visualization of more than 50 nodes could slow down the canvas update process.

The DO REST API

A RESTful API service is offered as a programmatic way to access the information found in the database. Metadata (in a richer version compared to the one accessible through the Web browser) can be downloaded in JSON format by using an HTTP request. As of May 2017, the request path can be built by concatenating to the DO's Web page URL (see 'Disease Ontology Web page' in Relevant Websites section) the string `"/api/metadata/"`, followed by the DOID of the term of interest. A query to this URL returns a JSON packet containing all the metadata for this term including parents, children, definition, external references, synonyms, name, alternate IDs and DO identifier. The DO team intends to broaden the types of services provided through API commands in the near future.

The screenshot shows the DO Web interface. At the top, there is a search bar with the text 'atypical autism' and a 'Go' button. To the right of the search bar is a link for 'Advanced Search'. Below the search bar, there is a 'Navigation' panel on the left and a 'Metadata' panel on the right.

Navigation Panel: It shows a hierarchical tree view of the Disease Ontology. The tree starts with 'disease' at the top, followed by 'disease of mental health', 'developmental disorder of mental health', 'pervasive developmental disorder', 'autism spectrum disorder', and finally 'atypical autism' which is highlighted. Other branches include 'disease by infectious agent', 'disease of anatomical entity', 'disease of cellular proliferation', 'adjustment disorder', 'cognitive disorder', 'childhood disintegrative disorder', 'specific developmental disorder', 'dissociative disorder', 'factitious disorder', 'gender identity disorder', 'impulse control disorder', 'personality disorder', 'sexual disorder', 'sleep disorder', 'somatoform disorder', 'substance-related disorder', 'disease of metabolism', 'genetic disease', 'physical disorder', and 'syndrome'.

Metadata Panel: It displays information for the selected term 'atypical autism'. The information is organized into a table-like structure:

Metadata	
DOID	DOID:0060042
Name	atypical autism
Definition	An autism spectrum disorder that involves some autistic symptoms occurring after age 3 with an absence of all the traits necessary for a diagnosis of autism. http://counsellingresource.com/distress/autistic/autism-atypical.html , http://www.wisegeek.com/what-is-atypical-autism.htm , www.neurodevnet.ca
Synonyms	PDD [EXACT]
Relationships	is_a autism spectrum disorder

Below the metadata, there is a button labeled 'Visualize' and a link 'Add an item to the term tracker'.

Fig. 1 DO Web interface with search, navigation and display functions. The disease tree view displays the DO's hierarchical structure and top level parent nodes expandable to view subgraphs. The disease of mental health subgraph with its direct child terms is shown. Term metadata are displayed for the selected term atypical autism from the tree view (the term has been reached by expanding progressively developmental disorder of mental health, then pervasive developmental disorder, finally autism spectrum disorder).

Applications in Other Works

One of the first applications of the DO is documented in Osborne *et al.* (2009), where it was used as a controlled vocabulary to annotate the human genome in terms of diseases. The ontology was used to identify relevant diseases in Gene Reference Into Function (GeneRIF) (Mitchell *et al.*, 2003), with the goal to provide a comprehensive disease-to-gene annotation. This initiative used a preliminary version of the ontology, which at the time corresponded to a manually inspected subset of UMLS and included concepts from outside the UMLS disease/disorder semantic network (i.e., cancers, congenital abnormalities, deformities, and mental disorders). The DO was preferred to OMIM and MeSH for this purpose because it was able to provide larger coverage and more accuracy (its hierarchical structure brought more detailed information about the disease of interest).

The authors argue that the annotation of genes with the DO can enable many graphical and statistical applications (following the model of the Gene Ontology). As an example, (Osborne *et al.*, 2009) showed how visualizing all genes in the human genome with established links to four cancers types led to the identification of eleven genes in common between these four cancers. Such studies facilitate the identification of relevant targets or markers for diseases with common etiology or pathology.

Another use of the Disease Ontology has been described in Du *et al.* (2009), and presents DOLite, a lighter version of the ontology. The work is based on the observation that the DO Directed Acyclic Graph is highly appropriate for organizing a wide spectrum of data, but it is not optimal for specific applications, such as identifying disease-gene relationships. For this specific purpose, a pruned (slimmer) version of the graph is more useful for building a high-level functional summary from a gene list.

Human genes annotations using the DO were very verbose and difficult to interpret, while DOLite allowed a more compact annotation process (larger number of genes assigned to individual disease categories and, conversely, smaller number of disease categories assigned to individual genes).

The DO group manages other software development projects (mainly data access and exploration tools) working in parallel with the DO main project.

The Functional Disease Ontology (FunDO) (Osborne *et al.*, 2009) is a Web application used to measure the internal consistency of the DO, and its ability to functionally annotate a gene list with diseases. The input of FunDO is a list of genes; the output includes relevant diseases based on the statistical analysis of the Disease Ontology annotation database.

GeneAnswers (Feng *et al.*, 2017) is a Bioconductor package that provides an integrative interpretation of genes, examining the relationships between diseases, genes, and biological pathways.

Current Work and Future Goal

At the time of writing this article, the Disease Ontology team is focusing on improving the ontological soundness of the ontology, such as removal of plural terms and of upper case terms.

Work is being dedicated especially to the cancer node and the infectious disease node: restructuring the nodes to avoid redundancy in terms, making terms consistent with the style guidelines, creating textual definitions from other sources such as Wikipedia and the National Cancer Institute, and creating logical definitions that will allow the Disease Ontology to effectively communicate with other ontologies on a computational level. These logical definitions reference the ontologies: FMA, HPO, Cell Line Ontology (CLO) (Sarntivijai *et al.*, 2014), and other OBO Foundry candidate ontologies.

The DO team has chosen to move towards a multi-editor model, utilizing Protégé (Noy *et al.*, 2001) to organize the DO using the Web Ontology Language. This will enable more interoperability with the Human Phenotype Ontology, EBI's Ontology Working Group, Mouse Genome Informatics, and Monarch Initiative, among others. It will also facilitate DO's multiple inferred views through reasoning. The DO team also recognized the imperative need to provide definitions for all DO terms. As a future commitment, the curatorial and development teams will work to add a significant number of definitions to the ontology.

Furthermore, the DO team intends to use the DO paradigm for the creation of non-human organism disease ontologies. The paradigm is expandable: disease defined by the etiology and the affected body system are universally applicable principles for describing pathologies in model organism, plants with viral, bacterial, fungal, or parasitic infections, as well as inherited and acquired disease.

The DO will try and integrate disease prevalence (the proportion of a population that is affected) to augment DO's disease classification.

Finally, an enhanced DO API will allow users to perform any action that they can do interactively on the website via the API.

Use Case

The Disease Ontology diseases can be browsed using a visual graphical tool. Let us suppose that the user is interested in exploring the terms connected to the notion of "heart hypertension". He/she uses the full-text search, but no result is returned. He/she might then search only for the word "heart" and thus identify the entry "DOID:114, *heart disease*". By pressing the functionality "Visualize" on the right top corner of the metadata tab of the DO Web browser, the user can visualize on the canvas the portion of the DO graph that concerns *heart disease* as a central concept (red rectangle); its parent *cardiovascular system disease* is shown (green rectangle) linked through an *is_a* relation (Fig. 2).

Eight children of *heart disease* are shown through an aggregation (yellow circle with the '8' figure). By clicking on the yellow circle, the user can decide which child nodes he/she wishes to visualize. At this level, the entry *Hypertensive heart disease*, originally

Fig. 2 Term visualization in the DO Web browser, as a result of the full-text search of "heart".

```
{
  "definition": "\"A heart disease that is caused by high blood pressure.\""
  [url:http\\:\\en.wikipedia.org/wiki/Heart_disease,
  url:http\\:\\en.wikipedia.org/wiki/Hypertensive_heart_disease]",
  "xrefs": ["ICD10CM:I11", "ICD10CM:I11.9", "ICD9CM:402", "ICD9CM:402.9",
  "SNOMEDCT_US_2016_03_01:155297007", "SNOMEDCT_US_2016_03_01:194769003",
  "SNOMEDCT_US_2016_03_01:194772005", "SNOMEDCT_US_2016_03_01:64715009",
  "UMLS_CUI:C0152105"],
  "parents": [{"is_a", "heart disease", "DOID:114"}],
  "id": "DOID:11516",
  "name": "hypertensive heart disease"
}
```

Fig. 3 Example response to API request in JSON format.

meant by the user, appears as a possible choice. Let us assume that the user only selects this term of interest. Furthermore, he/she continues to expand the green nodes (ancestors of *heart disease*) to find out more information about the searched disease portion of the ontology. In this way, he/she might obtain, as an example, the excerpt of the graph shown in Fig. 2.

On a different scenario, let us suppose the user already knows the DOID of the disease of interest; in this case, he/she might as well use the DO REST metadata API by constructing an HTTP request in the format indicated in Section The DO REST API, by adding at the end of the URL "DOID:11516" (which identifies *Hypertensive heart disease*), he/she obtains the JSON object shown in Fig. 3.

As already mentioned in Section Current Work and Future Goal, the DO team intends to expand the functionalities that can be accessed through API requests.

Biographical Sketch

Anna Bernasconi received her Master's Degree in Computer Engineering in 2015 from Politecnico di Milano and a Master in Computer Science at the University of Illinois at Chicago in 2016. She is currently a PhD candidate at Politecnico di Milano, working in the field of data-driven genomic computing. Her research interests are in the area of bioinformatics data and metadata integration in order to support answering to complex biological queries. She is currently focusing on public repositories of open data, controlled biomedical vocabularies and ontologies.

Marco Masseroli received the Laurea degree in Electronic Engineering in 1990 from Politecnico di Milano, Italy, and the PhD degree in Biomedical Engineering in 1996, from the Universidad de Granada, Spain. He is associate professor in the Dipartimento di Elettronica, Informazione e Bioingegneria at Politecnico di Milano, and lecturer of Bioinformatics and Biomedical Informatics. He carried out research activity in the application of Information Technology to the medical and biological sciences in several Italian and international research centers. He has also been visiting professor in the Departamento de Anatomía Patológica, Facultad de Medicina at the Universidad de Granada, Spain, and visiting faculty at the Cognitive Science Branch of the National Library of Medicine, National Institute of Health, Bethesda. His research interests are in the area of bioinformatics and biomedical informatics, focused on distributed Internet technologies, biomolecular databases, controlled biomedical terminologies and bio-ontologies to effectively retrieve, manage, analyze, and semantically integrate genomic information with patient clinical and high-throughput genetic data. He is the author of more than 170 scientific articles, which have appeared in international journals, books, and conference proceedings.

Biological and Medical Ontologies: Human Phenotype Ontology (HPO)

Anna Bernasconi, Politecnico di Milano, Milan, Italy

Marco Masseroli, Polytechnic University of Milan, Milan, Italy

Introduction

The Human Phenotype Ontology (HPO) is an open source ontology developed collaboratively, that provides a standardized, structured, and controlled vocabulary of all phenotypic features that are encountered in human hereditary and other diseases, with focus on monogenic ones.

The initial goal of the HPO has been to provide researchers and clinicians that operate in the human genetics field with a well-defined, shared, ontological framework. This allows to both share clinical data and knowledge in a computer-readable standardized way and to apply computational analysis algorithms to explore the human phenotype.

Phenotypical abnormalities are meant to serve as a bridge that translates genome-scale biology concepts into disease-centered human biology concepts. Understanding human health and disease requires a systematic human and machine readable representation of the current knowledge on phenotypic variation. Since an ontology provides a conceptualization of the knowledge of a domain, the HPO can be used effectively in such a context.

To understand the use of the ontology in supporting computational analysis, let us suppose that different experiments are tagged with synonymous descriptions such as *generalized amyotrophy*, *generalized muscular atrophy*, and *muscular atrophy, generalized*. While a human user would have no uncertainties in attributing all these terms to the same concept, a regular programmatic search function would. This is a case in which the automatic attribution of all these terms to a unique standardized ontological term becomes necessary. Indeed, an ontology that captures phenotypic information allows the use of computational algorithms that exploit semantic similarity between related phenotypic abnormalities, in correlation with other cellular phenomena associated with human disease.

In short, relevant uses of this ontology include: 1. providing a standardized vocabulary for clinical databases, 2. mapping between model organism and human phenotypes, 3. Bioinformatics research on the relationships between cellular/biochemical networks and human phenotypic abnormalities, 4. clinical diagnostics in human genetics.

All terms of the HPO have a unique stable identifier (e.g. HP:0000478), along with a label and a set of synonyms. Most terms also feature a textual definition manually curated by clinical experts. Moreover, HPO terms contain external references to other resources, aiming at an improved interoperability among different research areas in the biomedical field.

In its last release (Köhler *et al.*, 2016), the HPO is organized in five independent sub-ontologies that represent different aspects: *Mode of inheritance*, *Mortality/Aging*, *Clinical modifier*, *Frequency*, and the largest category of *Phenotypic abnormalities*.

When the first version of the HPO was developed (Robinson *et al.*, 2008), the most important source of information in the field of hereditary diseases was the database Online Mendelian Inheritance in Man (OMIM) (Hamosh *et al.*, 2005), which represented an essential result for the human genetics community. The HPO was therefore based on OMIM's terminology. However, OMIM did not use a controlled vocabulary to describe phenotypic features (signs and symptoms). This shortly made OMIM a wrong candidate for computational analysis. Note that, even if the OMIM entries were grouped by organ system, its data structure did not reflect that, for example, *Hypoplastic philtrum* and *Smooth philtrum* were more closely related to one another than to *Hypoplastic nasal septum* (all these descriptions are in the NOSE category of OMIM's clinical synopsis).

The creation of the HPO has thus answered to the need for a uniform and internationally accepted set of terms describing the human phenotype, and to the need for resources that would allow computational analyses on human phenotype data. With respect to the former one, it is noted that the terms used by clinicians to describe phenotypic expression have evolved in disorganized ways, which has resulted in the absence of databases of systematically collected phenotypic information about humans with hereditary disease. With respect to the latter one, it is clear intuitively that certain hereditary disorders are phenotypically similar to each other because of shared phenotypic features. However, these kinds of inference would have been impossible without a proper way to correlate the phenotype to features of genetic networks on genome-wide scale.

The HPO was born with the purpose to overcome previous efforts on computational analysis of phenotypic data in human hereditary disease. These works have used text mining techniques, but they all used concepts from thesauri (such as Unified Medical Language System (UMLS) (Bodenreider, 2004) or Medical Subject Headings (MeSH) (Lipscomb, 2000)) whose indexing terms are not designed for describing hereditary diseases and their related phenotypes.

Compared to previous works, HPO authors contend that a manually curated ontological approach to computational phenotype analysis has its own advantages. To mention one, in HPO terms are based on medical knowledge instead of text-mining inferences. These can be refined and extended in the future.

Note that integrative analysis like the one performed by the molecular biology community following the successful model proposed by the Gene Ontology (Ashburner *et al.*, 2000), was not possible in the human genetics community until the contribute of the HPO. Just as Gene Ontology, which is keeping expanding today, the HPO continuously undergoes active improvement. It is

currently being developed within the context of the Monarch Initiative (McMurry *et al.*, 2016), a collaboration between various research institutions supported by the National Institute of Health, which directs its efforts towards the integration of genotype-phenotype data from many species and sources. Moreover, the HPO participates in the OBO (Open Biological Biomedical Ontologies) Foundry project (Smith *et al.*, 2007), which holds an updated version of the ontology file on its server, available for download.

Furthermore, it is worth mentioning that the HPO project has been completely incorporated into the UMLS and is partnering with Orphanet (Rath *et al.*, 2012), a European Consortium of 40 countries providing a unique resource that gathers and improves knowledge on rare diseases. Their disease terms are being re-annotated with HPO terms.

The ontology is exposed as an open source resource in several platforms such as BioPortal (Noy *et al.*, 2009), the OBO Foundry (Smith *et al.*, 2007), MSeqDR browser (Falk *et al.*, 2015), the Ontology Lookup Service (Cote *et al.*, 2008), Ontobee (Ong *et al.*, 2017), and the Monarch Initiative, that provide intuitive Web-tools to browse its content.

The following of this chapter is organized as follows: Section “Development” defines the historical development of the ontology since its first version, born in 2007, until its release at the time of writing this chapter, in 2017. Section “The Human Phenotype Ontology” describes the core part of the HPO project, the structure of the ontology. Section “Phenotype Annotation Data” presents its main employment, the annotations of diseases. Section “Computable Definitions Of HPO Terms” includes relevant information on computer readable definitions of the ontology terms. Section “Quantitative Aspects” gives a quantitative perspective on the coverage and mappings provided by the HP ontology in its different releases. Section “Technological Details” overviews the technological aspects regarding its access. Section “Applications In Other Works” presents a list of notable applications that employ the HPO in their work. Finally, Section “Use Case: The Phenomizer” concludes with a sample use case scenario describing a simple activity of a user taking advantage of the HPO.

Development

The story of the HPO is made of three milestones, along with important literature material. This section proposes a brief overview of the phases that have brought the ontology from its birth to how it is today.

Robinson *et al.* (2008) and Robinson and Mundlos (2010) document the first release and use of the Human Phenotype Ontology. The initial intent was to enable the integration of phenotype information across scientific fields and databases. That version of the HPO made possible to annotate and analyze hereditary disease, using computational assertions stating that a disease is associated with a given phenotypic abnormality.

In 2014 the HPO upgraded its relevance, becoming a tool that allowed more interoperability, being utilized as a world-wide reference for describing phenotype information in various datasets (Köhler *et al.*, 2014a). At that stage, the ontology gained the dignity of a multi-dimension project (which still is), for linking molecular biology and disease through phenotype data. The project provided a richer standard phenotype terminology and collection of annotations of diseases with phenotypes. The project had clearly grown in terms of coverage, complexity, usage, and cross-linking with other projects. The 2014 version of the ontology was organized in three initial independent sub-ontologies which covered different categories. The largest is the *phenotypic abnormalities* sub-ontology, followed by the *mode of inheritance* and the *onset and clinical course* sub-ontologies. With respect to previous versions, the HPO at this point featured detailed textual definitions for 65% of the terms (created by clinical experts) and cross-references to other ontologies for 39% of the terms. In addition, to improve semantic interoperability with other ontologies in the OBO Foundry, the HPO project had started since 2009 to create logical definitions for each term. These are formal descriptions that are computer processable, useful for automated logical inference and reasoning. Finally, this release of the ontology also provided a number of negative annotations (NOT-modifier) denoting which clinical features have *not* been observed in a patient with a certain disease.

The release described in Köhler *et al.* (2016) has further reviewed the progress of the HPO project by adding specific areas of interest (e.g., common diseases), new algorithms for genomic discovery driven by phenotype information, and mapping with cross-species ontologies (e.g., Mammalian Phenotype Ontology (Smith *et al.*, 2005)). Also the quality control pipeline has been improved and user-friendly terminology has been added.

At the beginning of 2017 continues improving. As of May 2017, the BioPortal page lists 10 projects using this ontology: National Data Bank for Rare Diseases (BNDMR), the Clinical Genomicist Workstation (Sharma *et al.*, 2013), DisGeNET-RDF (Piñero *et al.*, 2017), Epidemic Marketplace (Silva *et al.*, 2010), Gemma (Zoubarev *et al.*, 2012), International Fanconi Anemia Registry (Kutler *et al.*, 2003), Linking Open Data for Rare Diseases (Choquet *et al.*, 2015), Neurocarta (Portales-Casamar *et al.*, 2013), SKELETOME (Groza *et al.*, 2012), and the Monarch Initiative.

The Human Phenotype Ontology

The Human Phenotype Ontology is arranged as a directed acyclic graph (DAG). The *terms* (or *concepts*) of the ontology are here interchangeably referred to as *classes*. Each term describes a phenotypic abnormality, while the ontology does not describe diseases themselves, but the abnormalities connected to them - therefore to be explored. Each term is related to its parent term through an “is a” relationship, meaning that it represents a *subclass* (i.e., more specific instance) of a more general parent term. Since a term in a DAG can have multiple parents, then a phenotypic feature can be considered as a more specific aspect of one or more parental

terms. As an example, from [Fig. 1](#): *Atrial septal defect* is a term which is more specific than both *Abnormality of cardiac atrium* and *Abnormality of the atrial septum*.

The HPO was first constructed with OBO-Edit ([Day-Richter et al., 2007](#)), an ontology editor for biologists. As a start, concepts and their representative terms were extracted by parsing the textual descriptions provided in omim.txt, a file version of the OMIM database.

Since OMIM does not use a controlled vocabulary, the terms were then curated manually, taking advantage of domain knowledge in human genetics (especially for the task of fusing synonyms into a single term). As an example, the three OMIM descriptions *Carpal bone hypoplasia*, *Hypoplasia of carpal bones*, and *Hypoplastic carpal bones* were fused into the single term *HP:0001498, Carpal bone hypoplasia*. Finally, additional descriptions were mapped using an adapted version of the Smith-Waterman algorithm of identification of common molecular subsequences ([Smith and Waterman, 1981](#)), then examined manually.

Such ontological structure for expressing information of the phenotype has a relevant advantage: search procedures can exploit the semantic relationships between terms.

Organization

Note that the majority of HPO classes describe abnormalities, but additional sub-ontologies are included to describe other aspects. At the time of writing this chapter, the HPO is divided into five independent sub-ontologies, which cover the following contents:

1. The Phenotypic abnormality sub-ontology is used to describe organ abnormalities and contains most terms; examples of terms at the first level are *Abnormality of the musculoskeletal system*, or *Hematological abnormality*;
2. The Mode of inheritance sub-ontology defines disease models according to Mendelian/non-Mendelian inheritance modes and contains terms like *Autosomal dominant*;
3. The Mortality/Aging sub-ontology expresses the age of death associated with a disease or observed in a specific individual to be annotated; example classes are *Neonatal death*, or *Sudden death*;
4. The Clinical modifier sub-ontology provides terms to characterize and specify the phenotypic abnormalities defined in the Phenotypic abnormality sub-ontology, with respect to various aspects including the speed of progression, the variability, or the onset; example classes include: *Onset in childhood*, *Rapidly progressive*, or *Incomplete penetrance*;
5. The Frequency ontology indicates the frequency of clinical feature display from patients, such as *Obligate*, *Frequent*, or *Occasional* (as identically defined in Orphanet).

Phenotype Annotation Data

The HPO is used for the annotation of databases such as OMIM, which is a catalogue of human genes and genetic disorders, Orphanet, a knowledge base about rare diseases, and DECIPHER ([Bragin et al., 2014](#)), an RNAi screening project.

Diseases are annotated to terms of the HPO, which are used to comprehensively describe signs, symptoms, and phenotypic manifestations that characterize the referred disease.

The HPO does not describe disease entities, but only the phenotypic abnormalities associated with them. To annotate all entries of OMIM that feature a clinical-synopsis section (nearly 6000 out of 8500), the most specific possible terms of the ontology have been used.

The true-path rule ([Gene Ontology Consortium, 2001](#)) applies to the terms of the HPO, i.e., a disease that is directly annotated to a specific term is also annotated (implicitly) to all its ancestors. As an example, *LARSEN SYNDROME* (OMIM:150250) is directly annotated to *Atrial septal defect* and is thereby implicitly annotated to *Abnormality of the atrial septum*, and to all its other ancestors' terms shown in [Fig. 1](#). Such structure of the HPO allows flexible searches for disease entries based on phenotypic abnormalities, that can be specified with different granularity focus (from broad to narrow).

The HPO project uses an ontological similarity measure to define a significant phenotypic similarity metric among hereditary diseases listed in OMIM. Following the example of the Gene Ontology, in the HPO terms that are closer to the root are more general than terms further away from the root (in [Fig. 1](#), *Atrial septal defect* is more specific than *Abnormal heart morphology*).

The information content of a HPO term is estimated using its frequency among the annotations of the entire OMIM corpus. The higher a term is located in the ontology, the lower information content it holds. For example, when two diseases such as *FIBROCHONDROGENESIS 1* and *TRANSALDOLASE DEFICIENCY* are both annotated to a term with high information content like *Patent foramen ovale*, then the degree of similarity calculated between these diseases is higher than the degree of similarity calculated between *FIBROCHONDROGENESIS 1* and *HYPERCALCEMIA, INFANTILE*, since these are annotated to the more general term *Abnormal heart morphology* (with lower information content). For a term t of the ontology, given its probability p (which is retrieved as its frequency among annotations to all the annotated diseases), the information content is equal to $(-\ln p(t))$.

A measure of similarity which is comparable to the one between two proteins, expressed in [Pesquita et al. \(2008\)](#), was applied on the diseases listed in the OMIM database.

Fig. 1 Example excerpt of the HPO structure regarding the Patent foramen ovale specific concept and all its associated general concepts in the HPO, together with the OMIM diseases annotated to them.

An ontology like the HPO is not intended to capture quantitative aspects such as the specific height of an adult body or the blood glucose level in mg/dl. Instead, its terms often express qualitative information regarding the excess or reduction in quantity of the entity in question (e.g., *Tall stature*, or *Hypoglycemia*). In some cases, it has been considered useful for clinical purposes to divide entities in multiple categories. For this purpose, a set of meta-annotations has been included as a support to HPO phenotype annotations. These include:

- Qualifier/Modifier. As an example, the degree of Intellectual disability is reported in six possible categories (i.e., Mild, Moderate, Severe, Profound, Borderline, or Progressive);
- Evidence Code (i.e., inferred by text mining, from published clinical study, individual clinical experience, electronical annotation, traceable author statement);
- Onset modifier (i.e., any term from the HPO sub-ontology Clinical modifier such as Ameliorated by, Triggered by, Aggravated by, etc.);
- Frequency modifier (i.e., any term from the HPO sub-ontology Frequency, such as percentage values, ratios, very rare, rare, occasional, frequent, typical, etc.).

Applications of the Annotations

A study from [Goh et al. \(2007\)](#), performed on 727 diseases (divided among 21 physiological-disorder classes), has led to an interesting visualization of the human phenome, a clustering of diseases based on their phenotypic similarities. The similarity of diseases is shown on its phenotypic level by linking all pairs of diseases exceeding a similarity score threshold. To better visualize these relationships, a graph representation has been used. The graph features a node for every disease and the distance between nodes expresses their similarity measure. A specific algorithm was used to show the clustered structure of the phenotypic network.

The study has demonstrated that, although diseases are generally independent of the disorder classes, the resulting phenotypic network displays clusters corresponding to many of these classes.

This representation additionally allows to visualize interconnections between one disease cluster and the other (e.g., muscular disorders are strongly connected to neurological disorders) ([Fig. 2](#)).

Another interesting application of HPO terms annotations was performed in a clinical setting. In medical genetics, clinical diagnosis is often pursued by combining multiple features. Automatized procedures must consider various dimensions: the number of hereditary disorders, the multitude of partially overlapping clinical features associated with them, and the different ways and levels of detail that clinicians may use to express clinical features.

Taking all these aspects into consideration, the aim is for diagnostic algorithms that are completely automatized, able to search medical diagnosis at varying levels of detail, weighting specific features more than general ones, and not very sensitive to the

Fig. 2 Visualization of an excerpt of the human phenome. Each disease listed in OMIM is shown as a node in the graph. The colors are assigned based on the membership to a disorder classes. The nodes are clustered in a phenotypic network. Connections between nodes are shown starting from a certain similarity score.

absence of individual features. An ontological approach appears appropriate in this context. Experiments on a set of 2116 OMIM diseases have shown in [Robinson et al. \(2008\)](#) that the HPO is able to capture phenotypic similarity at various levels of detail and that its calculation is not overly sensitive to the set of initial terms chosen for the search of the diagnosis. Given a set of features and asking for a possible diagnosis, in the optimal case the algorithm assigns a top rank to the original disease or at least place it in the first positions.

Computable Definitions of HPO Terms

An HPO term is explicitly related to other classes of the ontology through hierarchical relationships. However, no information is encoded about its relationships with concepts from cellular physiology, biochemistry, pathology, histology, and anatomy. For example, there is no link between a concept such as *Cerebral calcification* and the anatomical site *human brain*. This connection needs to be instructed through a computer-readable explanation. This is given through logical definitions created using the Phenotypic Quality Ontology (PATO) ([Gkoutos et al., 2005](#)). The basic methodology, described in [Köhler et al. \(2013\)](#), states that classes in the HPO are logically equivalent to descriptions based on Qualities (i.e., types of characteristic that the genotype affects), Entities (types of entities that bear the quality), and Modifiers. An example of such definition (in Manchester syntax) follows:

```
Class: Hypoglycemia
EquivalentTo: 'decreased concentration' (PATO: 0001163)
and towards some 'glucose' (ChEBI: 17234)
and inheres_in some 'portion of blood' (UBERON: 0000178)
and qualifier some 'abnormal' (PATO:0000460)
```

This statement means that the HPO term *Hypoglycemia* is defined as the intersection of all classes that are “a concentration which is lower relative to the normal or average”, “deviate from the normal or average”, with respect to (towards) glucose and inhering in “blood”.

This definition uses terms from multiple ontologies, including PATO for describing qualities, UBERON ([Mungall et al., 2012](#)) for describing anatomy, and ChEBI ([Hastings et al., 2013](#)) for describing small biological molecules. Definitions in this form can be used in various applications, such as automation of ontology construction, computational quality control, and integrative cross-species phenotype comparisons.

Quantitative Aspects

Literature contributions report precise quantitative measures regarding the coverage of the HPO ontology terms and of its annotations.

In [Robinson and Mundlos \(2010\)](#) the HPO contained over 9500 terms describing phenotypic features. On the website, they also provided about 50,000 annotations to HPO terms for 4779 diseases. This was a first step, which was immediately refined and expanded (including new terms definitions for concepts not originally found in the OMIM data).

The first Nucleic Acids Research database article regarding the HPO (Köhler *et al.*, 2014a) referred that the HPO included 10,088 terms and 13,326 relations between them. Additionally, the ontology provided textual definitions for 6603 terms and 6265 synonyms. Logical definitions were developed for 46% (4591) of all HPO classes using terms from other ontologies regarding anatomy, cell types, function, embryology, pathology and other domains. Also, the annotation database was updated to include 110,301 annotations of 7354 human hereditary syndromes present in OMIM, Orphanet and DECIPHER to classes of the HPO. On average, each disease entry had 15 HPO annotations.

The HPO has shown a substantial growth in the September 2016 release (documented in Köhler *et al.* (2016)). 11,813 terms have been included, linked through 15,595 relationships. The textual definitions have reached 8627 units, and the synonyms are 14,328. Logical definitions are included for 5717 HPO classes, referring to additional ontologies for biochemistry, gene function, and others.

As a novelty, also annotations of HPO terms to common disease have been added (until 2014, the focus of the HPO had been on rare disease). In this release, there are 123,724 annotations of HPO terms to rare diseases and 132,620 to common diseases.

At the time of writing of this chapter, in May 2017, according to the most updated version, the HP ontology has 12,358 concepts in total. According to the BioPortal profiling, the maximum number of children for a single term is 32. On average, a term has around three children. There exist 1037 terms with only one child, which represents a specialization nomenclature for that term. There are 22 terms with more than 25 children. 6702 classes have no definition, while the other 9102 present a definition curated by a clinical expert.

Mapping with Other Ontologies

The HPO has mappings to 185 other ontologies (as reported by the interoperability study shown in BioPortal webpage (Salvadores *et al.*, 2013)). The biggest overlapping is reported with OMIM, where 3608 concepts of HPO coexist, followed by the Suggested Ontology for Pharmacogenomics (Coulet *et al.*, 2006) (2633 overlapping concepts) and the Human Disease Ontology (2154).

As to other biomedical ontologies of broad interest, we mention that the HPO has 709 overlapping concepts with the Mammalian Phenotype Ontology (Smith *et al.*, 2005), 423 with the Mouse Pathology Ontology (Sundberg *et al.*, 2008), and 12 with the Foundational Model of Anatomy (Rosse and Mejino, 2003).

Köhler *et al.* (2014a) points out that 39% (3956) of the HPO terms contain cross-references, whose 98% points to Unified Medical Language System and Medical Subject Headings. Above all, these references are helpful for linking to the Disease Ontology resource.

Since the 2014 release, equivalence mappings to other phenotype vocabularies have been made available. These include the London Dysmorphology Database (LDDb) (Guest *et al.*, 1999) – which provides a direct conversion from LDDb phenotypic data into HPO terms, Orphanet – which is annotating all its diseases with HPO terms, MedDRA (Brown *et al.*, 1999), and phenoDB (Hamosh *et al.*, 2013).

These can be retrieved on the GitHub repository of the HPO in csv, and tsv formats.

The OBO-version files of the ontology contain HPO terms annotated with cross-references to UMLS, SNOMED CT (Donnelly, 2006) and MeSH concepts (e.g., “xref: SNOMEDCT_US:32659003”, or “xref: UMLS:C0266295”).

Coverage

Until 2013 not much attention has been dedicated to the terminological characteristics of the HPO and to the representation of phenotypes in standard terminologies. In Winnenburger and Bodenreider (2014) the authors have evaluated the 2014 release of the HPO against the UMLS and its source vocabularies, including SNOMED CT and MeSH, observing that the coverage of the HPO phenotype concepts in the UMLS is 54% and only 30% in SNOMED CT.

Technological Details

HPO Workflow and Resources

Hudson, a system for continuous integration, is used for the management of stable releases of the data of the HP ontology (in addition to other related metadata). The major focus is on the phenotype ontology and the annotation data, but closely related projects are included too.

The files kept available through Hudson include the OBO and OWL formats of the ontology, the logical definitions of HPO terms, mappings to other phenotype vocabularies (e.g., Orphanet, LDDb, MedDRA), manual and semi-automatic annotations of syndromes from OMIM, DECIPHER, and Orphanet, and disease-HPO term associations asserted not to be associated with the corresponding disease (negative annotation: NOT-modifier).

In addition, the system offers access to: the mapping of human genes to phenotypic features and vice versa, a precomputed disease-disease similarity matrix for all diseases with annotations to HPO terms, and a cross-species phenotype ontology (human, mouse, zebrafish).

Access Mode

The HPO data content can be currently accessed through flat files (with OBO or OWL extensions). To download the most recent stable releases, the users should use persistent URLs that redirect to the continuous integration systems Hudson and Jenkins.

Other methods to access the HPO information include a MySQL database (which is a dump of all HPO related data) and Web-based tools (among others, the HPO features a browser with free text search functionality on its main Web page).

Choosing concepts through the Web interface leads to an individual page for each HPO term. Alternatively, the same page is accessible by adding an id parameter to the home page URL of the HPO (e.g., id=HP:0000127 shows the *Renal salt wasting* page).

Each page presents the term label, its synonyms, the textual and logical definitions, a list of super- and sub-classes, lists of associated diseases and genes (exportable to Excel or CSV format), and the associated graph view.

The last stable release files of the ontology can be also downloaded through the BioPortal page (in the formats OBO, CSV, and XRDF) and the OBO Foundry portal (OBO and OWL formats).

Furthermore, the Monarch Initiative provides a useful integrated interface in which each phenotype trait is directly shown as linked to the diseases that feature it, the genes that characterize it, the related genotypes, and the liked variants.

In addition to simple browsing, the HPO official Web page allows requesting new classes, suggesting structural changes of the HPO hierarchy (through the HPO tracker), accessing the GitHub repository, and reading the documentation.

Applications in Other Works

Apart from being a resource for computational analysis of human disease phenotypes, the HPO has been used as a basis for a wide range of studies and tools that perform analysis in both research and clinical settings.

One of the main application fields of the HPO corresponds to the development of algorithms and computational tools for phenotype-driven differential diagnosis.

The *Phenomizer* is a Web-based application used for clinical diagnostics which uses searches in ontologies based on semantic similarity. Köhler *et al.* (2009) presents the initial version of the tool, which has now been updated to the latest HPO.

In April 2017, the HPO website has also made available a new beta-prototype called *Orphamizer*, which uses a different algorithm (the Bayesian Ontology Query Algorithm – BOQA (Bauer *et al.*, 2012)), a different set of diseases and phenotype-associations.

In the context of phenotype-driven exome and genome analysis, novel tools that provide results of Next Generation Sequencing results include *PhenIX* (Zemojtel *et al.*, 2014), which provides effective diagnosis of genetic disease by computational phenotype analysis of the disease-associated genome, *Exomiser* (Robinson *et al.*, 2014), which uses a set of phenotypes encoded using the HPO, and *Phevor* (Singleton *et al.*, 2014), which combines biomedical ontologies to identify disease-causing alleles.

Cross-species phenotype analysis include *MouseFinder* (Chen *et al.*, 2012), *PhenoDigm* (Smedley *et al.*, 2013), *PhenomeNET* (Hoehndorf *et al.*, 2011), as well as *Uberpheno* (Köhler *et al.*, 2013). These enable searches for novel disease genes based on the analysis of model-organism phenotypes. *PhenogramViz* (Köhler *et al.*, 2014b) allows to explore in a visual fashion gene-to-phenotype relations in copy number variants (CNVs).

Clinical data management and analysis tools include *ECARUCA* (Vulto-van Silfhout *et al.*, 2013), *DECIPHER* (Bragin *et al.*, 2014), and *PhenoTips* (Girdea *et al.*, 2013).

As a method for Functional and network analysis (inferring novel drug indications) we mention *PREDICT* (Gottlieb *et al.*, 2011).

Use Case: The Phenomizer

An indirect use of the ontology can be made through the *Phenomizer*, described in the previous section. As an example of how the HPO has been designed to be used in practical cases, this section reports a procedure for using an ontological semantic similarity analysis in clinical diagnosis.

A search procedure has been designed to take phenotype features as input and provide possible disease (diagnosis) as output.

The semantic structure of the HPO is used to weight the importance of the input phenotype features and disease terms according to their clinical specificity. Intuitively, when a physician enters the query term *downward slanting palpebral fissures*, the amount of clinical information about the patient is higher than when the physician enters the term *abnormality of the eyelid*.

The designed search procedure takes this fact into account by weighting the best match between a query term to the terms of any given disease according to the information content of that term. A statistical model assigns a p-value to the results of each search. Not only a ranking, but also a significance threshold for search results is provided. This distinguishes this search procedure from other search routines commonly used in clinical genetics that are designed to show all diseases that are characterized by a certain number of query terms.

In a practical scenario, the user enters the HPO term in the *Features* window. Let us suppose he/she selects various phenotypic features of the disease “ADACTYLIA, UNILATERAL” (e.g., *Brachydactyly syndrome*, *Clinodactyly of the 5th finger*, *Cone-shaped epiphyses of the middle phalanges of the hand*, *Polydactyly*, *Short 1st metacarpal*, *Short 2nd finger*, *Short 3rd finger*, *Abnormality of the fingernails*). Each feature may be marked as mandatory if the clinician is certain of its presence and especially of its relation with the underlying disease. Logically, when a feature is marked as mandatory, all the diseases that are not annotated to it are removed from the reasoning base.

Suppose the user marks as mandatory the features “Short 2nd finger” and “Short 3rd finger”.

When the *Phenomizer* is initiated, a list of differential diagnoses ranked according to p-value is shown.

The list of the first 10 candidates indeed includes “ADACTYLIA, UNILATERAL” as foreseen, with the same 0.0020 p-value as “CAMPTOBRAHYDACTYLY”, “BRACHYDACTYLY TYPE A3” and other 5 diseases, along with two other entries with 0.0032 p-value.

Such output returned by the *Phenomizer* can prompt more appropriate clinical examination or technical examinations with respect to the one given by the clinician in a non-automatized way.

Biographical Sketch

Anna Bernasconi received her Master's Degree in Computer Engineering in 2015 from Politecnico di Milano and a Master in Computer Science at the University of Illinois at Chicago in 2016. She is currently a PhD candidate at Politecnico di Milano, working in the field of data-driven genomic computing. Her research interests are in the area of bioinformatics data and metadata integration in order to support answering to complex biological queries. She is currently focusing on public repositories of open data, controlled biomedical vocabularies and ontologies.

Marco Masseroli received the Laurea degree in electronic engineering in 1990 from Politecnico di Milano, Italy, and the PhD degree in biomedical engineering in 1996, from the Universidad de Granada, Spain. He is associate professor in the Dipartimento di Elettronica, Informazione e Bioingegneria at Politecnico di Milano, and lecturer of bioinformatics and biomedical informatics. He carried out research activity in the application of Information Technology to the medical and biological sciences in several Italian and international research centers. He has also been visiting professor in the Departamento de Anatomía Patológica, Facultad de Medicina at the Universidad de Granada, Spain, and visiting faculty at the Cognitive Science Branch of the National Library of Medicine, National Institute of Health, Bethesda. His research interests are in the area of bioinformatics and biomedical informatics, focused on distributed Internet technologies, biomolecular databases, controlled biomedical terminologies and bio-ontologies to effectively retrieve, manage, analyze, and semantically integrate genomic information with patient clinical and high-throughput genetic data. He is the author of more than 170 scientific articles, which have appeared in international journals, books, and conference proceedings.

Biological and Medical Ontologies: Systems Biology Ontology (SBO)

Anna Bernasconi and Marco Masseroli, Politecnico di Milano, Milan, Italy

© 2019 Elsevier Inc. All rights reserved.

Introduction

In the last decades, data relevant to molecular and cellular biology has grown enormously, encouraging Systems Biology approaches, which use computational modelling as a means to understand large amounts of diverse information. In order to exchange and reuse models in appropriate ways, the community relies on standards for biological quantitative models' curation with increasing interest. Using computational modelling to describe and analyze biological systems has thus become a fundamental activity of Systems Biology.

While common data formats such as Systems Biology Markup Language (SBML) (Hucka, 2013) or Cell Markup Language (CellML) (Lloyd *et al.*, 2004) have answered to the need for exchange and integrate models on a syntactic level (encoding them in agreed formats), the community has highlighted a growing need for an additional semantic layer. Note that the semantic layer is not necessary in general for model simulations; however, it enhances the ability to understand and analyze models in a programmatic way. One of the efforts in this direction has been concretized with the Minimal Information Requested in the Annotation of Models (Le Novère *et al.*, 2005), a set of rules for curating quantitative models of biological systems. Nevertheless, semantic integration is a goal typically pursued through the use of an ontology.

The Systems Biology Ontology (SBO) has been therefore designed to provide semantic information and characterization of the model components, in addition to annotate the results of biochemical experiments to facilitate their resourceful use. While existing ontologies already covered the biological aspects described by models, the SBO takes care of encompassing this idea to model-related aspects. Indeed, one of the objectives of the SBO is to simplify the direct identification of the relation between one of the components of a model and the structure of the overall model, increasing the usability and re-usability of the model. The annotation of a model can be performed at all stages of its lifecycle, when considered convenient. As an example, the model creator might be interested in providing information about its constructions, built-in assumptions, and the framework in which the model was conceived. A following modeler, after running multiple simulations, may find useful to add information such as a definition of the nature of the parameters, specific rate laws that can be applied, the mathematical expressions that govern the behavior of the instantiated system. Finally, also a biological investigator could enrich the data about the model by specifying the participants' role in reactions encoded in the model.

At the time of writing this article, the SBO is a set of seven controlled, relational vocabularies of terms that are hierarchically organized. The effort made by the SBO team to standardize the encoding of semantics for models (both discrete and continuous) in systems biology was first conceived during the 9th SBML Forum Meeting in Heidelberg on October 14–15, 2004. In that occasion, it was observed that much of the knowledge necessary to understand and simulate a model was only held by modelers (it was not encoded in SBML, indeed). A solution to this problem, by creating a controlled vocabulary to store this information, was proposed by Nicholas Le Novère shortly after. The idea of the SBO has appeared for the first time in Le Novère (2005) and the SBO is now a well-established software tool, publicly available, and shared with free consensus.

SBO is a candidate ontology of the Open Biomedical Ontologies (OBO) Foundry, available to use for free. SBO is a project of the BioModels.net effort, which defines agreed-upon standards for model curation. Its development is organized as a collaboration among the BioModels.net team (EMBL-EBI, United Kingdom), the Le Novère lab (Babraham Institute, United Kingdom), and the SBML team (Caltech, United States). The ontology is also open to contributions toward its development from the community. For requesting new terms creation or suggesting existing terms modifications, the users can exploit dedicated trackers that are available on SBO SourceForge project (see 'SourceForge page' in Relevant Websites section). As to contacting the team that develops SBO, they manage a mailing list for general discussions about BioModels.net projects which works by email subscription. SBO benefited from the funds of the European Molecular Biology Laboratory and the National Institute of General Medical Sciences.

In June 2017, at the time of writing this article, the BioPortal (Noy *et al.*, 2009) website lists 3 projects using this ontology: MaSyMoS, a Neo4J instance containing SBO data along with other bio-ontologies, models, and simulation descriptions (Henkel and Waltemath, 2014), Systems Biology Graphical Notation (SBGN), a visual language that allows the representation of networks of biochemical interactions (Le Novère *et al.*, 2009), and SBML, the standard exchange format for computational models already mentioned.

The following of this article is organized as follows: Section Development defines the historical development of the ontology since its 2006 version, until its state at the time of writing this article, in June 2017. Section The Systems Biology Ontology describes the SBO with focus on its structure, terms, and relations. Section Interoperability and Quantitative Aspects overviews interoperability with other resources used in Systems Biology and outlines quantitative aspects on the coverage and mappings provided by the SBO. Section Technological Details describes the technological aspects regarding its access, search functionalities, implementation, API, and changes management. Section Applications in Other Works presents a list of other applications that employ the SBO, or contribute to common pipelines. Finally, Section Use Case concludes with a use case scenario describing a simple activity of a user taking advantage of the SBO.

Development

The version of the SBO documented in Le Novère paper (Le Novère, 2005) mentions the introduction of the SBO within a big international initiative: BioModels.net, along with MIRIAM and BioModels Database (Li *et al.*, 2010a).

The SBO intended to be a first hierarchical structuring of knowledge on the matters of Systems Biology and the underlying models. Its main purpose was to facilitate the direct identification of the relation between a model component and the model structure. It presented three different vocabularies: a classification of rate laws (e.g., *Mass action*, *Henri-Michaelis-Menten kinetics*), a taxonomy of the roles of reaction participants (e.g., *substrate*, *catalyst*, *inhibitor*), and a terminology for parameter roles in quantitative models (e.g., *Hill coefficient*, *Michaelis coefficient*). The innovative aspect of such ontology, compared to more classical ones such as the Gene Ontology, was that the links in SBO crossed the vocabulary barriers. For instance, a term which defined a rate-law was allowed to have children representing the relevant reacting species parameters.

Using SBO terms to annotate model components was an essential step for annotation methods to be compliant with the standard indicated by MIRIAM and also influenced the search strategies used by models databases (such as BioModels Database).

Le Novère (2006) presented an improved version of the ontology, which featured four different vocabularies. One new branch, referring to the three previous ones from Le Novère (2005), was added to include a list of modelling frameworks that precise how to interpret a mathematical expression (e.g., *deterministic*, *stochastic*, *boolean*). This subset of terms, used within SBML, would allow to get rid of explicit mathematics in the model itself, downloading a correct and updated rate-law in its place.

Le Novère *et al.* (2006) documents a renovated version of the SBO which had by then become part of the OBO Foundry. The development team planned to export the ontology not only in OBO flat format, but also in OBO-XML (containing the same information that OBO-flat, expressed in eXtensible Markup Language) and in OWL (Web Ontology Language). At that moment, the ontology was able to index, define, and relate terms based on five different vocabularies. A branch for the classification of events represented by biochemical models (e.g., *binding*, *transport*, *degradation*) had been added with respect to the version of Le Novère (2006).

Li *et al.* (2010b) described the increased use of the SBO through a solid implementation and organization of their Web services, which improved the interoperability of the ontology.

At the time of writing this article, the SBO website exhibits an updated 'News' page containing detailed chronological facts regarding the ontology evolution, from its first steps in 2006 until the latest major updates, in 2013.

Courtot *et al.* (2011) is a reference community paper which covers the ontologies developed by BioModels.net, including the SBO. In this article, other domain ontologies, such KiSAO and TEDDY (Knüpfer *et al.*, 2009) are described. They are employed to characterize aspects of the systems' dynamic behaviors.

The Systems Biology Ontology

The SBO consists of seven orthogonal vocabularies each represented by a *branch* of the ontology, connected to the root of the ontology by a *is_a* relationship. As of June 2017, they appear on the Tree browsing section on SBO page (see 'SBO website' in Relevant Websites section) in the following form (also synthesized in Fig. 1):

1. SBO:0000236 – *physical entity* representation branch: the physical nature of the entity, that can be either *material* (e.g., *macromolecule*, *physical compartment*, *observable*) or *functional* (e.g., *transporter*, *enzyme*, *receptor*);
2. SBO:0000003 – *participant role* branch: the roles played by reaction participants (e.g., *reactant*, *product*, *modifier*);

Fig. 1 SBO terms are distributed in seven orthogonal branches, as described in Section The Systems Biology Ontology. In the graph, the arrows with a continuous line represent simple *is_a* relationships, while the arrows with a dashed line indicate that intermediate terms are omitted.

3. SBO:0000231 – *occurring entity representation* branch: the type of occurring interaction, in terms of types of *process* (e.g., *composite biochemical process, molecular, or genetic interaction*) and the *relationship* that an entity represents with respect to another (e.g., *inhibition or stimulation*);
4. SBO:0000064 – *mathematical expression* branch: the mathematical expressions describing the system (e.g., *enzymatic rate law, mass-action rate law, Hill-type rate law*);
5. SBO:0000004 – *modelling framework* branch: the modelling framework within which the model was constructed, critical to recognize the possible limitations under different simulation conditions (e.g., *discrete framework, concrete framework, logical framework*);
6. SBO:0000545 – *system description parameter* branch: quantitative parameters to describe the systems (e.g., *Michaelis constant, catalytic constant, thermodynamic temperature*);
7. SBO:0000544 – *metadata representation* branch: the types of metadata represented within model components (e.g., *annotation, bibliographical reference*).

The user should note that the terms in the *system description parameter* and *mathematical expression* branches contain Mathematical Markup Language (MathML) Version 2 mathematical expressions (Ausbrooks *et al.*, 2003), which allow to remove ambiguities in the semantic meaning. These are used to relate the symbols used in the model expressions to the actual parameters referenced in the ontology.

SBO Term Fields

Table 1 reports all the fields regarding a single term that the ontology stores and makes available for manual and programmatic exploration. As an example, the specific values for the term *catalytic rate constant* are shown.

The identifiers are made by the “SBO” prefix, followed by a colon separator and a 7-digit identifier (e.g., SBO:1234567). A SBO identifier is assigned to a term when it is introduced in the ontology and characterizes that concept term permanently, although some of the information connected to it (such as its name, definition, or other fields) may change over time. When a term needs refinement, the central concept is not affected, only further clarified. When new terms are introduced, it often becomes necessary to change relationships with existing *child* and *parent* terms that must be refined to allow conceptual distinction between them.

In sporadic cases, a term is considered obsolete because it does not fit anymore in the SBO domain of interest. Such situation can happen when the term in question: (1) is out-dated, (2) becomes redundant because the same concept is represented by an improved term, (3) becomes redundant because another term covers the same concept space, (4) was created by mistake.

When a term becomes obsolete, it is not visible anymore in the ontology. Nevertheless, it is not removed from the downloadable ontology files (in which it is marked with the property *is_obsolete*: true) and Web browser (in which they are marked with the tag “(OBSOLETE TERM)” in red beside the SBO identifier), to still allow for its search. When applicable, terms that can be used in alternative to the obsolete term are proposed.

Table 1 Description of SBO term fields and their example values for the term SBO:0000025 – catalytic rate constant

Field	Meaning	Optional	Example
Identifier	The SBO identifier appears at the top of the pop up display (marked obsolete in case of obsolete terms).		SBO:0000025
Name	The full name of the SBO term.		catalytic rate constant
Synonyms	Known synonyms for the term name.	X	kcat, turnover number
Definition	Textual definition describing the precise meaning and context of use for the selected term.		Numerical parameter that quantifies the velocity of an enzymatic reaction.
MathML	A standardised XML-based mathematical definition of the term.	X	
Rendered equation	The graphically rendered representation of the mathematical definition presented in the MathML field, if applicable.	X	
Comment	Clarification comments inserted by the curator to further define or clarify the use of the term		“irreversible” removed on March 11, 2007 by Nicolas Le Novère
Miscellaneous	Creation and last modification dates for the term.		<i>Date of creation</i> : 13 February 2006, 23:41 <i>Date of last modification</i> : 11 March 2007, 21:39
Parents	Hyperlinked SBO identifier(s), and term name(s) of the immediate parent(s) of the displayed term.		SBO:0000035 forward unimolecular rate constant, continuous case (is_a)
Children	Hyperlinked SBO identifier(s), and term name(s) of the immediate children of the displayed term		SBO:0000320 product catalytic rate constant (is a) SBO:0000321 substrate catalytic rate constant (is a)
History	Lists the dates, actions and details of all changes to the displayed term, since its introduction to the ontology.		11/03/200: term updated. Some information about this term have been updated 13/02/2006: term created. This term has been newly created

Fig. 2 MathML expression for SBO:0000282 – dissociation constant term, contained in the definition field of the OBO file of the SBO.

SBO Relationships

Terms are arranged within a branch of the SBO ontology using only *is_a* relationships (subsumptions), which entail that each term is a particular version of its parent term (e.g., *boolean switch* is *a switch value*).

The terms contained in different SBO vocabularies (of the available seven ones) are not directly linked to each other. However, some terms of the ontology contain MathML (see ‘MathML 2.0’ in the Relevant Websites section) lambda functions that contain links to terms belonging to other branches. As an example, [Fig. 2](#) reports the MathML entry for the *dissociation constant*.

Interoperability and Quantitative Aspects

At the time of writing this article, in June 2017, according to the most updated version, the Systems Biology Ontology featured 648 concepts in total, 21 of which are considered obsolete.

Among the various defined formats within which computational models can be encoded in order to be annotated with SBO concepts, SBML, CellML, and GENESIS ([Bower and Beeman, 1998](#)) are worth mentioning. SBML, in particular, provides a specific integration mechanism to accept SBO terms that can be integrated into its file format (the attribute *sboTerm* is specifically used for linking SBO term annotations with model components).

According to the interoperability study shown in BioPortal website ([Salvadores et al., 2013](#)), as of June 2017, notable overlapping is observed with the Computational Neuroscience Ontology ([Le Franc et al., 2012](#)), MeSH (in its Robert Hoehndorf Version) ([Lipscomb, 2000](#)), and the National Cancer Institute (NCI) Thesaurus ([Sioutos et al., 2007](#)), where many concepts of SBO coexist. These are followed by the Neuroscience Information Framework (NIF) Standard Ontology ([Bug et al., 2008](#)), the BioModels Ontology ([Hoehndorf et al., 2011](#)), and SNOMED CT ([Donnelly, 2006](#)). Overlaps with other notable ontologies can be found in: Gene Expression Ontology (126 terms) ([Barrett et al., 2013](#)), Gene Ontology (50 terms), International Classification of Diseases, Version 10 (32 terms) (see ‘ICD, World Health Organization’ in Relevant Websites section) ([Rath et al., 2012](#)), and the Mammalian Phenotype Ontology (24 terms) ([Smith et al., 2005](#)).

Technological Details

The back-end system on which the SBO is based is a MySQL relational database management system. This is accessed through a front-end Web interface built on Java Server Pages and Java Beans. The content uses UTF-8 encoding, thus supporting a broad set of characters within terms and their definitions.

Access Mode

SBO is an open-resource ontology (therefore listed on SourceForge), developed and maintained by the scientific community, whose files are reusable under the terms of the Artistic License 2.0. This means that it is permitted to copy and distribute verbatim copies of it, but changes are not allowed (see ‘License’ in Relevant Websites section).

Instant exports are automatically generated daily at 7.00 am United Kingdom time (or on specific request), and they can be directly downloaded through the specific page in the website (see ‘SBO download’ in the Relevant Websites section). They are available in OBO (full and no MathML versions), OWL and XML formats. In addition, the XML (and MathML) schemas used by the SBO are provided. In the same Web page, a minimal ‘Statistics’ tab is provided, i.e., a summary display which specifies the date of the last modification to the ontology.

The Systems Biology Ontology can also be explored by using the public interface Web browsers in the European Bioinformatics Institute (EBI) website (see ‘SBO website’ in Relevant Websites section), the National Center for Biomedical Ontology (NCBO) BioPortal (see ‘SBO BioPortal’ in Relevant Websites section) ([Noy et al., 2009](#)), or the OBO Foundry website (see ‘SBO OBO Foundry’ in Relevant Websites section), which provides the download of the OWL version of the ontology.

Search and visualization of a specific SBO term

The EBI SBO website offers a dedicated resource to curate and maintain the SBO. The SBO search box is available in all pages of the SBO website in the top right corner. The text entered in the search box can be used to find keywords in the fields identifier, name, definition, synonyms, MathML, and comment of SBO terms. Results are provided as a list of tables created based on what the entered text has matched in the term information (i.e., Terms with a match in the *accession*, Terms with a match in the *name*, Terms with a match in the *definition*, *comment* or *mathML*, Terms with a match in the *synonym*). Each table features the SBO Accession, its term name, and clickable links to the tree and entry view of that term.

The search is conjunctive (searched words are combined through the logical operator AND), meaning that when more than one word is entered in the search box, the results will only include terms where all words appear within an SBO term. The disjunctive search (which allows the logical OR between words) and more advanced kinds of searches are envisioned as future works.

The SBO can be also browsed as an ontology tree, accessible through the Browse function on the Web page (see 'SBO website' in Relevant Websites section). The tree can be navigated by expanding and collapsing its branches, using the icons marked with plus and minus symbols, respectively, positioned on the left side of each sub-tree. By clicking on a term, the user can open a pop up display that contains the specific information for that particular entry (known as the entry view), which includes the fields specified in Section SBO Term Fields.

Alternatively, the entry view of specific terms can be directly accessed using dedicated URLs, built by appending the SBO identifier of the term to the SBO website URL.

The SBO Rest API

To allow programmatic access to the terms and sub-trees of the ontology from other software tools, the SBO team provided a first (soon to be discontinued) version of Web Services whose communication layer had been implemented based on Apache Axis. The updated version uses instead a new Web Services stack (JAX-WS). From the SourceForge project Web page, a runnable Java library can be downloaded, useful to communicate with the SBO Web Services in a Java program.

The services use official SBO identifiers (such as SBO:0000135) as input parameters for all available methods. The implementation is based on a simple *Term* Java Object class, which represents the concept of the ontology and features all the fields of the ontology terms as described in Section SBO Term Fields. The output returned by each service is given as a null or not-empty list of objects.

The possible queries include the ability to retrieve SBO terms (either only one or a list of them, as the subtree of a given term) described in XML and OWL format, or just as a simple OBO object. As an example, the method *getTerm*(SBO:0000192) retrieves the term corresponding to the given identifier, i.e., *Hill-type rate law, generalised form*. This will be in the form of an object which contains all the information stored in the ontology about the associated identifier. On the other hand, *getOWLTerm*(SBO:0000192) retrieves the OWL format of the same term with all its information.

It is possible to request: direct children and parents of a term, the whole sub-tree starting from a term, a check that a term is a (direct) child of another one, a check that a term is obsolete, or a check that a term corresponds to the SBO root. For instance, *getTreeOWL*(SBO:0000009) retrieves the subtree starting from the term *kinetic constant* (whose identifier is SBO:0000009), in the OWL format.

Search for terms can be made on the whole content of the ontology (e.g., with *searchOWL()*), on the possible completions of the word(s) given in the search parameter (e.g., with *searchPossibleCompletions()*), on the Details, MathML, Name, or Synonyms sections of the terms (e.g., with *searchStringTermMath()* and *searchTermDetailsOWL()*).

Changes and Tracking

Distributed curation is made possible by using a custom-tailored locking system allowing concurrent access. This system allows a continuous update of the ontology with immediate availability and suppress merging problems.

Requests for new terms, changes, and additional features can be made through the tracker tool provided in the SourceForge page, along with reports of errors in existing terms. They are evaluated by an SBO curator, with possible contact of the submitter for clarification purposes. Other issues should be addressed to the email contacts provided on the SBO website.

At the time of writing this article, the SBO presented no versioning system, which is considered as one of the future additional features. The only way to identify what version an ontology file represents is by looking at the *data-version* field at the top of the file downloadable on the website (see 'SBO Downloads' in the Relevant Websites section).

In the Browse menu of the main website the user can access the "History" section, a list of recently added or updated terms. The same information can be found in the single SBO terms, under their history and comment fields.

Applications in Other Works

As mentioned in Section Introduction, the SBO is part of the BioModels.net project, that aims at integrating the collaborative use of the following three technologies: (1) MIRIAM, as a standard to curate and annotate models to facilitate their reuse, (2) the SBO, as a set of controlled vocabularies to be used to characterize the models' components, and (3) the BioModels Database, as a resource to store, search, and retrieve published models of interest. These resources, together with the language SBML, are supporting the productive exchange and reuse of computational models.

The interoperability of the SBO with the SBML has been set since the Level 2 Version 2 of the SBML, which now provides a mechanism to annotate model components with SBO terms. This mechanism increases the semantics of a model, enriching the information about its interaction topology and mathematical expression. *SBMLsqueezer* (Dräger *et al.*, 2008) is a modelling application that helps to identify SBO terms based on existing model components, with the aim to generate suitable mathematical relationships over biochemical maps. This is based on the automation of equations generation, overcoming the highly error-prone and cumbersome process of manually assigning kinetic equations, such as the Henri-Michaelis-Menten equation.

SemanticSBML (Krause *et al.*, 2010) is a tool that uses the SBO annotation to integrate individual models into a larger one. Furthermore, all graphical symbols used in the SBGN languages are linked to an SBO term, thus helping to generate SBGN maps from SBML models.

The Systems Biology Pathway Exchange (SBPAX) is an integration effort that allows SBO terms to be added to the Biological Pathway Exchange (BioPAX) format, which is linked to information useful for computational modelling, such as the quantitative descriptions contained in SBO.

Use Case

Li *et al.* (2010b) introduced the integrated use of the technologies of MIRIAM, SBO and BioModels Database as a unified toolkit to analyze biological mathematical models. Let us consider a typical example workflow that uses all three tools, by querying their services. The studied biological problem corresponds to the one introduced in Hong *et al.* (2009), i.e., the molecular mechanism underlying how DNA damage causes predominantly phase advances in the circadian clock.

Since the peer-reviewed journal where the (Hong *et al.*, 2009) study is published suggests to their authors to deposit their data into a public repository, Hong and colleagues submitted their model to the BioModels Database, where it is freely available (identified by the ID BIOMD0000000216). By means of the appropriate method of the BioModels Web Services, with the specification of the BioModels Database ID BIOMD0000000216 as a parameter, the user can retrieve the model encoded in SBML. Fig. 3 shows an excerpt from the retrieved XML file describing the model, specifically a part that is contained inside its *listOfSpecies* XML element tag.

In such a SBML representation, the user can find lists with all the computationally interesting components of the model, such as *listOfFunctionDefinitions*, *listOfCompartments*, *listOfSpecies*, *listOfParameters*, *listOfRules*, and *listOfReactions*, just to mention some.

Let us suppose that, among these many elements, the user is interested in understanding the nature of the SBML *species* denoted as “CP” (the one shown in Fig. 3, indeed). In order to examine it more in depth, he/she can look at the SBO term associated with it. As it can be observed in the *species* element of Fig. 3, the SBML *species* is associated with the attribute *sboTerm*: “SBO:0000252”. As indicated in Section The SBO Rest API, the SBO Web Service method *getTerm*(‘SBO:0000296’) can be used in such a case to retrieve more information about the term. It returns the full record of this term, which includes its name (i.e., *polypeptide chain*) along with other information, as shown in Fig. 4.

Whenever this should not be enough, the user should notice that an entity (i.e., the species “CP” in this example) is associated with some annotations (contained within the *annotation* XML element tags, see Fig. 3), encoded in RDF following the SBML specifications. This information can be used to further investigate the properties of this entity. For instance, in this example the user might want to find “CP” in the UniProt database (UniProt Consortium, 2015), whose entries can be retrieved from the MIRIAM Web Services. The user will need an identifier to search for further details on the UniProt Knowledge Base. In particular, the UniProtKB identifier O15516 can be extracted as the final part of the URL in the *rdf:li* XML element tag (see Fig. 3). By using the appropriate MIRIAM Web Service, the user can learn that “CP” is a *polypeptide chain* made of *Circadian locomotor output cycles protein kaput*.

This is an example of the information that can provide a better biological understanding of the biological mathematical model. The integrated use of the three modules of BioModels.net (i.e., MIRIAM, SBO and BioModels Database), in case together with

Fig. 3 Excerpt of the SBML encoded model from Hong *et al.* (2009). Note the usage of the attribute *sboTerm*.

Term: *SBO:0000252*

Name

polypeptide chain

Definition

Naturally occurring macromolecule formed by the repetition of amino-acid residues linked by peptidic bonds. A polypeptide chain is synthesized by the ribosome. CHEBI:16541

Comment

Name changed on January 10 2007 by Nicolas Le Novère, to disambiguate from non-ribosomal peptides. Created on November 10 2006 by Nicolas Le Novère.

Parent(s)

[SBO:0000246](#) information macromolecule (is a)

Miscellaneous

Date of creation: 10 November 2006, 15:38

Date of last modification: 10 January 2007, 13:49

History

Date	Action	Details
10/01/2007	term updated	Some information about this term have been updated
10/11/2006	term created	This term has been newly created

Fig. 4 Details of the SBO term: polypeptide chain (SBO: 0000252).

others, queried through dedicated Web Services, guarantees a way to fully understand the biology behind a computational biology model (which is specified in SBML and curated with the use of the SBO).

Biographical Sketch

Anna Bernasconi received her Master's Degree in Computer Engineering in 2015 from Politecnico di Milano and a Master in Computer Science at the University of Illinois at Chicago in 2016. She is currently a PhD candidate at Politecnico di Milano, working in the field of data-driven genomic computing. Her research interests are in the area of bioinformatics data and metadata integration in order to support answering to complex biological queries. She is currently focusing on public repositories of open data, controlled biomedical vocabularies and ontologies.

Marco Masseroli received the Laurea degree in Electronic Engineering in 1990 from Politecnico di Milano, Italy, and the PhD degree in Biomedical Engineering in 1996, from the Universidad de Granada, Spain. He is associate professor in the Dipartimento di Elettronica, Informazione e Bioingegneria at Politecnico di Milano, and lecturer of Bioinformatics and Biomedical Informatics. He carried out research activity in the application of Information Technology to the medical and biological sciences in several Italian and international research centers. He has also been visiting professor in the Departamento de Anatomía Patológica, Facultad de Medicina at the Universidad de Granada, Spain, and visiting faculty at the Cognitive Science Branch of the National Library of Medicine, National Institute of Health, Bethesda. His research interests are in the area of bioinformatics and biomedical informatics, focused on distributed Internet technologies, biomolecular databases, controlled biomedical terminologies and bio-ontologies to effectively retrieve, manage, analyze, and semantically integrate genomic information with patient clinical and high-throughput genetic data. He is the author of more than 170 scientific articles, which have appeared in international journals, books, and conference proceedings.

Ontology-Based Annotation Methods

Pietro H Guzzi, University "Magna Graecia" of Catanzaro, Catanzaro, Italy

Introduction

The production of experimental data in molecular biology has been accompanied by the accumulation of functional information about biological entities. Terms describing such knowledge are usually structured by using formal instruments such as controlled vocabularies and ontologies (Guzzi *et al.*, 2012). The Gene Ontology (GO) project (Harris *et al.*, 2004) has developed a conceptual framework based on ontologies for organizing terms (namely GO Terms) describing biological concepts. It consists of three ontologies: Molecular Function (MF), Biological Process (BP), and Cellular Component (CC) representing different aspects of biological molecules. Each GO Term may be associated with many biological concepts (e.g. proteins or genes) by a process also known as annotation. The whole corpus of annotations is stored in publicly available databases, such as the Gene Ontology Annotation (GOA) database (Camon *et al.*, 2004a).

In such a way records representing the associations of biological concepts, e.g. proteins, and GO terms may be easily represented as $\{P, T_1, \dots, T_n\}$, e.g. {P06727, GO:0002227, GO:0006810, GO:0006869} or {ApolipoproteinA-IV, innate immune response in mucosa, transport, lipid transport}.

The whole set of annotated data represents a valuable resource for the existing approach of analysis. From those, the use of association rules (AR) (Hipp *et al.*, 2000; Guzzi *et al.*, 2014; Zaki *et al.*, 1997) is less popular with respect to other techniques, such as statistical methods or semantic similarities (Cannataro *et al.* 2013, 2015). Existing approaches span from the use of AR to improve the annotation consistency, as presented in Faria *et al.* (2012), to the use of AR to analyse microarray data (Carmona-Saez *et al.*, 2006; Ponzoni *et al.*, 2014; Tew *et al.*, 2014; Benites *et al.*, 2014; Nguyen *et al.*, 2011; Manda *et al.*, 2013; Agapito *et al.*, 2016), (see Naulaerts *et al.*, 2013 for a detailed review).

As we pointed out in a previous work (Guzzi *et al.*, 2014), the use of AR presents two main issues due to the Number and Nature of Annotations (Huttenhower *et al.*, 2009). The number of annotation is for each protein or gene is highly variable within the same GO taxonomy and over different species. The variability is caused by two main facts: (i) The presence of various methods of annotations of data; and (ii) the use of different data sources.

Regarding the *Nature of Annotations*, it should be evidenced that the association between a biological concept and its related GO Term can be performed with 14 different methods. These methods are in general grouped into two broad categories: experimentally verified (or manuals) and Inferred from Electronic Annotation (IEA). IEA annotations are usually derived using computational methods that analyse literature. Each annotation is labelled with an evidence code (EC) to keep track of the technique used to annotate a protein with GO Terms. Manual annotations are, in general, more precise and specific than IEA ones (see Guzzi *et al.*, 2012). Unfortunately, their number is lower, and the ratio among IEA versus non-IEA is variable.

Often many generic GO terms (this is particularly evident when considering novel or not well-studied genes) annotate genes and proteins, and the problem is also referred to *Shallow Annotation Problem*. The role of these non-specific annotations is to suggest an area in which the proteins or genes operate. This phenomenon affects especially IEA annotations derived by using computational methods.

The Process of Ontology-Based Annotation

The process of annotation based on ontologies is structured on two main steps: from one side a structured vocabulary, or ontology, is continuously updated and stores annotation terms, from the other hand a set of methods (manually or automated) associated to biological terms (e.g. proteins) the set of related annotations. In the rest of the article, we explain this process using Gene Ontology and Disease Ontology.

Annotations in Gene Ontology

The GO is a structured vocabulary of terms (namely GO-terms) organised in three ontologies: Molecular Function (MF), Biological Process (BP) and Cellular Component (CC). Each GO-term is uniquely associated with a code. Each ontology describes a particular aspect of a gene or gene product functionality. Each gene or gene product is associated with a set of GO terms (Cho *et al.*, 2013).

Each gene is associated with a set of terms that describe its functionality, and this association is stored into the Gene Ontology Annotation Database (GOA) (Camon *et al.*, 2004b). Each annotation in the GO has a source which can be a literature reference, a database reference or computational evidence (Guzzi *et al.*, 2014). Each annotation is associated with an evidence code describing the process of annotation. There exist 18 evidence codes divided into four categories. It possible to see whether an annotation is supported by more than one type of evidence. The most reliable annotations are those inferred directly from experimental evidence. Since most researchers do add their findings to the GO, professional curators examining the literature

add these findings. The second big class of annotation method is the computational inference, out of which six imply manual curation (ISS, ISO, ISA, ISM, IGC, RCA). Finally, the evidence code IEA is used for all inferences made without any human supervision, regardless of the method used. The IEA evidence code is by far the most abundantly used evidence code. For an in-depth treatment of the topic, we refer the interested reader to some recent reviews. There exist seven different electronic annotation pipelines: Ensembl Compara, InterPro2GO, UniProtKB-Keyword2GO, UniProtKB-Subcellular, Location2GO, UniPathway2GO, EC2GO, and HAMAP2GO.

Retrieving Gene Ontology Annotations: The Gene Ontology Annotation Database

The Gene Ontology Annotation Database (GOA) stores the corpus of electronic and manual associations (annotations) of Gene Ontology (GO) terms to UniProt Knowledgebase (UniProtKB) entries. The GOA is accessible through the QuickGO interface. QuickGO is a web-based tool for searching and viewing GO terms and annotations from the GOA database. Through the use of the software, the user may see, filter and download all the annotation data. Annotation data within QuickGO are updated on a weekly basis. In parallel, the consortium offer web-services for accessing GOA-data at <http://www.ebi.ac.uk/QuickGO-Beta/webservices>.

Annotations in Disease Ontology

The Disease Ontology (DO) database (Schriml *et al.*, 2012) is a knowledge base related to human diseases. The current version stores information about 8043 diseases. DO aims to connect biological data (e.g. genes) considering a disease-centred point of view. The DO semantically integrates a disease and existing medical vocabularies. DO terms, and their DOIDs have been utilised to annotate disease concepts in several primary biomedical resources. The DO is organised into eight central nodes to represent cellular proliferation, mental health, anatomical entity, infectious agent, metabolism and genetic diseases along with medical disorders and syndromes anchored by traceable, stable identifiers (DOIDs). Genes may be annotated with terms coming from DO that may be freely downloaded from the website. DO is structured into a directed acyclic graph (DAG), and the terms are linked by relationships in a hierarchy organised by interrelated subtypes. DO has become a disease knowledge resource for the further exploration of biomedical data, including measuring disease similarity based on functional associations between genes, and it is a disease data source for the building of biomedical databases.

To transfer annotations from Disease Ontology to genes, the MetaMap Transfer tool (MMTx) was used. These mappings are stored in the Open Biomedical Ontologies format and can be manually edited using the open source graph editor DAGEdit <http://geneontology.sourceforge.net>.

Nomenclature

CA	Common ancestors	$IC_{d_{shared}}$	Disjoint shared information content
CE	Common entries	IC_{shared}	Shared information content
DCA	Disjunctive common ancestors	KOS	Knowledge organization systems
F_D	Frequency in a external dataset D	MICA	Most informative common ancestors
IC	Information content	SB	Semantic-base
		SSM	Semantic similarity measure

Introduction

The biological role of an entity is considered to be its semantics, which has been increasingly being represented through common vocabularies. The entries in these vocabularies represent biological features, that are often connected with each other by semantic relations, such as subsumption. The availability of these common vocabularies, and their usage to semantically annotate entities enabled the development of computational semantic similarity measures (Batet *et al.*, 2014). Before defining semantic similarity, we should start by defining why bioinformatics needs semantic similarity in the first place, then what it is, to finally describe how it can be calculated.

Why?

Biomedical entities, such as proteins or chemical compounds, are frequently compared to each other to find similarities that may able us to transfer knowledge from one another. In the case of proteins, one of the most popular techniques is to calculate sequence similarity by locating short matches between sequences and then generate local alignments (Smith and Waterman, 1981). In the case of compounds, one of the most popular techniques is to calculate the number of 2D substructural fragments (molecular fingerprints) that they have in common (Willett, 2011). The above techniques are popular mainly because they can be implemented by high performance tools, such as BLAST (Altschul *et al.*, 1997), and are based on simple, unambiguous and widely available digital representations. However, these digital representations result from observations of how these biomedical entities look like, and not about their semantics. This means that from these digital representations we cannot have a direct insight about their biological role. Sequence similarity and common fingerprints measure how close two entities are in terms of what they look like, which may differ from their biological role.

There is an association between what an entity looks like and its biological role, i.e., proteins with similar sequence tend to have similar molecular functions, as well as with compounds with similar molecular shapes. However, there are many exceptions. For example, crystallins have a high sequence similarity to several different enzymes due to evolution, but in the eye lens their role is to act as structural proteins, not enzymes (Petsko and Ringe, 2004). Another example is caffeine and adenosine. These two molecules have a similar shape, so similar that caffeine is able to bind to adenosine receptors (Gupta and Gupta, 1999). However, adenosine induces sleep and suppresses arousal while caffeine makes you more awake and less tired. Semantic similarity addresses the above exceptions, by comparing biomedical entities based on what they do and not on what they look like. This means that when looking for similar compounds to caffeine, other central nervous system stimulants, such as doxapram, will appear before adenosine that has the opposite effect.

What?

Digital representations of biomedical entities based on structure can normally be expressed using a simple syntax. For example, ASCII strings are used to represent: the nucleotide sequences of genes; the amino acid sequences of proteins, and also the structure of compounds using SMILES. Semantics is however more complex since it may have different interpretations according to a given context. For example, the meaning of a biological role of a given gene may differ from a biological or medical perspective. For humans the easiest way to represent semantics is to use free text due to its flexibility to express any concept. For example, short text comments are usually valuable semantic descriptions to understand the meaning of a piece of information. However, for computers free text is not the most effective form of encoding semantics, making semantic similarity measurement between different text descriptions almost unfeasible.

In recent years, the biomedical community made a substantial effort in representing the semantics of biomedical entities by using common vocabularies, which vary from simple terminologies to highly complex semantic models. These vocabularies are instantiated by Knowledge Organization Systems (KOS) in the form of classification systems, thesauri, lexical databases, gazetteers, and taxonomies, and ontologies (Barros *et al.*, 2016). Perhaps the most well-known KOS is the Gene Ontology, which has been

extensively used to annotate gene-products with terms describing their molecular functions, biological processes and cellular components, and the source of most semantic similarity studies in bioinformatics. This manuscript will denote a KOS used in a semantic similarity measure as its Semantic-Base (SB). Semantic similarity measures become feasible when a biomedical community accepts a SB as a standard to represent the semantics of the entities in their domain. Semantic similarity is therefore a measure of how close are the semantic representations of different biomedical entities in a given SB. This means that the semantic similarity between two entities depends on their SB representation and also on a similarity measure that calculates how close these representations are in the SB.

How?

We may think that given a SB, we should be able to find the optimal quantitative function to implement semantic similarity. However, the notion of semantic similarity is dependent on what are the objectives of the study. For example, a biologist and a physician may have two different expectations about the semantic similarity between the biological roles of two genes.

In bioinformatics, ontologies have been the standard SB for calculating semantic similarity. The SB provides an unambiguous context on where semantic representations can be interpreted. A semantic representation is sometimes referred as a set of annotations, i.e., a link between the entity and an entry in the SB. Each entity can have multiple annotations. This means that the similarity measure may be applied for multiple entries in the SB. There are also different types of annotations. For example, an annotation can represent a finding with experimental evidence, or just a prediction from a computational method. Semantic similarity can explore the different types of annotations, for example to filter out annotations in which we have lower confidence.

A similarity measure is a quantitative function between entries in the SB, which explores the relations between its entries to measure their closeness in meaning. An entry is normally connected to the other entries by different types of relations represented in the SB. The similarity measure calculates the degree of shared meaning between two entries, resulting in a numerical value. For example, this can be performed by identifying a path between both entries in the SB, and calculating the semantic gap encoded in that path. This means that a semantic similarity measure can be defined by the SB and the quantitative measure used, which will be formulated in the following sections.

Semantic Base

Definition 1: (Semantic-Base). A Semantic-Base is a tuple $SB = \langle E, R \rangle$, such that E is the set of entries, and R is the set of relations between the entries. Each relation is pair of entities (e_1, e_2) with $e_1, e_2 \in E$.

When using biomedical ontologies, the entries represent the classes, terms or concepts. This definition ignores the type of relations that may be present in the ontology, since semantic similarity measures are normally restricted to subsumption relations (*is-a*). Nevertheless, a measure may use other type of relation, or even use different types of relations. The interpretation of its results should take this into consideration. One of the reasons why subsumption relations are used is because they are transitive, i.e. if $(e_1, e_2) \in R$ and $(e_2, e_3) \in R$ then we can implicitly assume that (e_1, e_3) is also a valid relation. This enables us to define the ancestors and descendants of a given entry.

Definition 2: (Ancestors). Given a SB represented by the tuple $\langle E, R \rangle$, and T the transitive closure of R on the set E (i.e. the smallest relation on E that contains R and is transitive), the Ancestors of a given entry $e \in E$ are defined as $Anc(e) = \{a : (e, a) \in T\}$.

Definition 3: (Descendants). Given a SB represented by the tuple $\langle E, R \rangle$, and T the transitive closure of R on the set E , the Descendants of a given entry $e \in E$ are defined as $Des(e) = \{d : (d, e) \in T\}$.

There are multiple successful semantic similarity measures being used in bioinformatics. Many of them are inspired on the contrast model proposed by Tversky (1977), in the sense that they balance the importance of common features versus the exclusives. Thus, a semantic similarity measure can be categorized by how it defines the common features, and how it calculates the importance of each feature. The first step in most measures is to find the common ancestors in the SB to define the common features.

Definition 4: (Common Ancestors). Given a SB represented by the tuple $\langle E, R \rangle$, the Common Ancestors of two entries $e_1, e_2 \in E$ is defined as $CA(e_1, e_2) = Anc(e_1) \cap Anc(e_2)$.

Information Content

This manuscript follows an information-theoretic perspective of semantic similarity (Sanchez and Batet, 2011). To calculate the importance of each entry the measures identify the information content of each entry. Resnik (1995) defined the information content of an entry based on the notion of the entropy of the random variable X known in information theory (Ross, 2009). The intuition is to measure the surprise evoked by having an entry $e \in E$ in the semantic representation.

Fig. 1 This graph represents an example of a classification of metals with multiple inheritance, since *gold* and *silver* are considered both precious and coinage metals.

Definition 5: (Information Content). Given a SB represented by the tuple $\langle E, R \rangle$, and a probability function $p : E \rightarrow]0,1]$, the information content of an entry $e \in E$ is defined as $IC(e) = -\log(p(e))$.

The probability function should be defined in a way that bottom-level entries in the SB become more informative than top-level entries, making the $IC(e)$ correlated with the specificity of e in the SB.

The definition of the probability function p can follow two different approaches:

Intrinsic: p is based only on the internal structure of the SB.

Extrinsic: p is based on the frequency of each entry in an external dataset.

Considering the graph represented in **Fig. 1** as our SB, and assuming an intrinsic approach $p(e) = \frac{Desc(e)+1}{|E|}$, then we have all the bottom entries with p equal to $\frac{1}{8}$, $p(coinage) = \frac{4}{8}$, $p(precious) = \frac{5}{8}$, and $p(metal) = \frac{8}{8}$. Thus, we have $IC(metal) < IC(precious) < IC(coinage) < IC(platinum) \dots < IC(copper)$. Note also that the addition of 1 to avoid having a zero probability for the entries without descendants.

Definition 6: (Frequency). Given a SB represented by the tuple $\langle E, R \rangle$, and an external dataset D , and a predicate $refer(d, e)$ that is true when a data element $d \in D$ refers the entry $e \in E$, then the frequency of a given entry in that dataset is defined as

$$F_D(e) = |\{d : refer(e, d) \wedge d \in D \wedge e_1 \in Desc(e) \cup \{e\}\}|$$

Note that when using subsumption relations, i.e., an occurrence of an entry, it is also an implicit occurrence of all its ancestors.

Definition 7: (Extrinsic Probability). Given a SB represented by the tuple $\langle E, R \rangle$, and a frequency measure F_D the extrinsic probability function of an entry $e \in E$ is defined as

$$p(e) = \frac{F_D(e) + 1}{\max\{F_D(e_1) : e_1 \in E\} + 1}$$

Note that top-level entries have high frequency values due the occurrences of their descendants, so their IC is close to zero. Note again the addition of 1 this time in both parts of the fraction to avoid having a zero probability.

Considering again the graph represented in **Fig. 1** as our SB, and assume an external dataset D containing exactly one occurrence of each entry, then we have all the bottom entries with F_D equal to $\frac{2}{9}$, $F_D(coinage) = \frac{5}{9}$, $F_D(precious) = \frac{6}{9}$, and $F_D(metal) = \frac{9}{9}$. Thus, we again have $IC(metal) < IC(precious) < IC(coinage) < IC(platinum) \dots < IC(copper)$. We will assume this IC instantiation for the remainder examples in this manuscript.

Shared Ancestors

Not all ancestors are relevant when calculating semantic similarity since some of them are already subsumed by others and do not represent any new information. So normally the measures select only the most informative ones.

Definition 8: (Most Informative Common Ancestors). Given a SB represented by the tuple $\langle E, R \rangle$, and an IC measure, the Most Informative Common Ancestors of two entries $e_1, e_2 \in E$ is defined as

$$MICA(e_1, e_2) = \{a : a \in CA(e_1, e_2) \wedge IC(a) = \max\{IC(a_1) : a_1 \in CA(e_1, e_2)\}\}$$

Considering again the graph represented in [Fig. 1](#) as our SB, and the extrinsic IC defined above, then we have $MICA(palatium, copper) = \{metal\}$, $MICA(silver, gold) = \{coinage\}$, and $MICA(palatium, gold) = \{precious\}$.

Sometimes the most informative common ancestors are not sufficient, since they may neglect multiple inheritance relations. Thus, instead of MICA, the measures can use the disjunctive common ancestors ([Couto and Silva, 2011](#)).

Definition 9: (Disjunctive Common Ancestors). Given a SB represented by the tuple $\langle E, R \rangle$, and an IC measure, and a function $PD: E \times E \times E \rightarrow \mathbb{N}$, that calculates the difference between the number of paths from the two entries to one of their common ancestors, the Disjunctive Common Ancestors of two entries $e_1, e_2 \in E$ is defined as

$$\begin{aligned} DCA(e_1, e_2) = \{a : \\ a \in CA(e_1, e_2) \wedge \\ \forall a_x \in CA(e_1, e_2) PD(e_1, e_2, a) = PD(e_1, e_2, a_x) \\ \Rightarrow IC(a) > IC(a_x)\} \end{aligned}$$

Considering again the graph represented in [Fig. 1](#) as our SB, the extrinsic IC defined above, then we have $DCA(silver, gold) = \{coinage, precious\}$, and $DCA(platinum, gold) = \{precious, metal\}$.

Shared Information

The importance of common features is defined by the shared IC present in the common ancestors, normally its average.

Definition 10: (Shared Information Content). Given a SB represented by the tuple $\langle E, R \rangle$, and an IC measure, the Shared Information Content of two entries $e_1, e_2 \in E$ is defined as $IC_{shared}(e_1, e_2) = \overline{IC(a) : a \in DCA(e_1, e_2)}$.

Note that DCA can be replaced by MICA, however since all ancestors in MICA have the same IC value by definition only that IC value is used in practice.

Considering again the graph represented in [Fig. 1](#) as our SB, the extrinsic IC defined above, then when using MICA we have $IC_{shared}(platinum, gold) = -\log(\frac{6}{9})$. If we use DCA then we have $IC_{shared}(platinum, gold) = (-\log(\frac{6}{9}) - \log(\frac{2}{9}))/2$.

More recently, [Ferreira et al. \(2013\)](#) proposed the usage of the disjointness axioms in semantic similarity by defining the disjoint shared information content. The idea is that if we know that two entries are disjoint, then we should decrease their amount of shared information.

Definition 11: (Disjoint Shared Information Content). Given a SB represented by the tuple $\langle E, R \rangle$, a set of axioms A , and an IC_{shared} measure, the Disjoint Shared Information Content of two entries, $e_1, e_2 \in E$ is defined as $IC_{dshared}(e_1, e_2) = IC_{shared}(e_1, e_2) - k(e_1, e_2)$ with $k: E \times E \rightarrow \mathbb{N}$ satisfying the following conditions: i) $k(e_1, e_2) > 0$ if e_1 and e_2 are disjoint according to A ; ii) $k(e_1, e_2) = 0$ if otherwise.

Similarity Measure

Definition 12: (Semantic Similarity Measure). Given a SB represented by the tuple $\langle E, R \rangle$, a Semantic Similarity Measure is a quantitative function $SSM: E \times E \rightarrow \mathbb{R}$.

Note that a semantic similarity measure is not expected to be instantiated by the inverse of a metric or distance function, but the following conditions are normally satisfied:

non-negativity: $SSM(e_1, e_2) \geq 0$ with $e_1, e_2 \in E$;

symmetry: $SSM(e_1, e_2) = SSM(e_2, e_1)$ with $e_1, e_2 \in E$.

Many measures are also normalized, i.e., $SSM(e_1, e_2) \in [0..1]$ with $e_1, e_2 \in E$; and $SSM(e, e) = 1$ with $e \in E$.

The seminal work based on Resnik's measure ([Resnik, 1995](#)) was one of the first measures to be successfully applied to a biomedical ontology, namely the Gene Ontology ([Lord et al., 2003](#)). The measure was defined as:

$$SSM_{resnik}(e_1, e_2) = IC_{shared}(e_1, e_2)$$

Another well-known measure, was defined by Lin *et al.* (1998) as:

$$SSM_{lin}(e_1, e_2) = \frac{2 \times IC_{shared}(e_1, e_2)}{IC(e_1) + IC(e_2)}$$

where the denominator represents the exclusive features.

Note that both measures are independent of using *MICA* or *DCA* as the common features.

Considering again the graph represented in Fig. 1 as our SB, the extrinsic *IC* defined above, and *MICA*, then we have $SSM_{resnik}(platinum, gold) = -\log(\frac{6}{9})$ and $SSM_{lin}(platinum, gold) = (2 \times -\log(\frac{6}{9})) / (-\log(\frac{2}{9}) - \log(\frac{2}{9}))$.

Entity Similarity

Until now we only defined *SSM* in terms of entries, but a biomedical entity may not be directly represented in the SB, but instead linked to the SB through annotations. For example in the case of proteins, they are not represented as entries of the Gene Ontology but through annotations. In opposition, chemical compounds are represented as entries of the ontology Chemical Entities of Biological Interest (ChEBI).

Definition 13: (Annotation). Given a SB represented by the tuple $\langle E, R \rangle$ and a set of biomedical entities B , a predicate $annotates(b, e)$ that is true when the entity $b \in B$ is annotated with the entry $e \in E$, then the annotation set of a biomedical entity (or concept) $b \in B$ is defined as

$$AS(b) = \{e : e \in E \wedge annotates(b, e)\}$$

This definition ignores the type of annotation, e.g. with experimental or computational evidence, since the similarity measure calculation is usually independent of this information. It is up to the user to decide which type of annotations to include.

To compare biomedical entities we need to extend the *SSM* definition so it applies to the two sets of entries of each entity, instead of a single entry for each entity. For readability we will use the same function name *SSM*, to represent different functions according to the input domain, i.e. two entries or two sets of entries.

There are multiple successful instantiations of entity semantic similarity measures, and most of them use two aggregate functions (e.g., average, maximum) on the results from comparing each pair of entries annotated to each entry.

Definition 14: (Aggregate Measure). Given a SB represented by the tuple $\langle E, R \rangle$, a set of biomedical entities B , two aggregate functions f and g , and two biomedical entities $b_1, b_2 \in B$ the Aggregate Similarity Measure is defined as

$$SSM_{aggregate}(AS(b_1), AS(b_2)) = f(\{g(\{SSM(e_1, e_2) : e_1 \in AS(b_1)\}) : e_2 \in AS(b_2)\})$$

Considering again the graph represented in Fig. 1 as our SB, f as the average function, g as the maximum function, two entities containing metals $B = \{\alpha, \beta\}$, and their respective annotation set $AS(\alpha) = \{platinum, palladium\}$ $AS(\beta) = \{copper, gold\}$, then we have

$$\begin{aligned} SSM_{aggregate}(\{platinum, palladium\}, \{copper, gold\}) &= avg\{ \\ &\quad max\{SSM(platinum, copper), SSM(platinum, gold)\}, \\ &\quad max\{SSM(palladium, copper), SSM(palladium, gold)\}\} \end{aligned}$$

Another popular approach is to apply the Jaccard coefficient to all common entries vs. the exclusive ones.

Definition 15: (Jaccard Measure). Given a SB represented by the tuple $\langle E, R \rangle$, a set of biomedical entities B , an annotation set AT , and two biomedical entities $b_1, b_2 \in B$ the similarity measure is defined as

$$\begin{aligned} SSM_{jaccard}(AS(b_1), AS(b_2)) &= \\ &\frac{\sum \{IC(e) : e \in \{Anc(e_1) : e_1 \in AS(b_1)\} \cap \{Anc(e_2) : e_2 \in AS(b_2)\}\}}{\sum \{IC(e) : e \in \{Anc(e_1) : e_1 \in AS(b_1)\} \cup \{Anc(e_2) : e_2 \in AS(b_2)\}\}} \end{aligned}$$

Considering the example above of α and β when using Jaccard we will have

$$\begin{aligned} SSM_{jaccard}(\{platinum, palladium\}, \{copper, gold\}) &= \\ &\frac{IC(precious) + IC(metal)}{IC(coinage) + IC(precious) + IC(metal)} \end{aligned}$$

Future Directions

This manuscript is focused on defining semantic similarity using a single KOS, however a large amount of biomedical resources use multiple KOS describing a single domain from different perspectives or even distinct domains. Calculating semantic similarity

using multiple KOS as SB is a complex problem, and only a few works have addressed it (Solae-Ribalta *et al.*, 2014). Thus, a future formulation of multiple domain semantic similarity is much required.

Another issue is about the incompleteness of KOS. They normally represent work in progress, being updated as our knowledge of the domain becomes more sound and comprehensive. Keeping a KOS up-to-date is also a daunting task in terms of human effort, especially in large KOS, so we should always expect to have a delay until new knowledge is incorporated. This means that the common features identified in a KOS may be incomplete, and the exclusives features may not even be exclusive in the future. If a biomedical entity is not annotated with a specific feature, that does not mean that the entity does not have that feature, it only means that we do not know if it has or not. Thus, a future formulation of semantic similarity that takes in account the incompleteness of KOS is also much required.

Closing Remarks

This manuscript presented a definition of semantic similarity following an information-theoretic perspective that covers a large number of the measures currently being used in bioinformatics. It defined the amount of information content two entries share in a SB, and how it can be extended to compare biomedical entities represented outside the SB but linked through a set of annotations.

The manuscript aims at providing a generic and inclusive formulation that can be helpful to understand the fundamentals of semantic similarity and at the same time be used as a guideline to distinguish between different approaches. The formulation did not aim at providing a one size fits all definition, i.e. trying to represent all measures being proposed.

The manuscript presented well-known measures in bioinformatics, Resnik, Lin and Jaccard coefficient, according to the proposed definitions. It also presented their results when applied to simple example of a classification of metals, which is used along the text to clarify the definitions being presented. Finally, a software repository (see Relevant Website section) is available to test and learn more on how semantic similarity works in practice.

Biographical Sketch

Francisco M. Couto is currently an associate professor with habilitation and vice-president of the Department of Informatics of FCUL, member of the coordination board of the master in Bioinformatics and Computational Biology, and a member of LASIGE coordinating the Health and Biomedical Informatics research line. He graduated (2000) and has a master (2001) in Informatics and Computer Engineering from the IST. He concluded his doctorate (2006) in Informatics, specialization Bioinformatics, from the Universidade de Lisboa. He was on the faculty at IST from 1998 to 2001 and since 2001 at FCUL. He was an invited researcher at EBI, AFMB-CNRS, BioAlma during his doctoral studies. In 2003, he was one of the first researchers to study semantic similarity based on information content in biomedical ontologies. In 2006, he also developed one of the first systems to use semantic similarity to enhance the performance of text mining solutions. In 2011, he proposed the notion of disjunctive common ancestors. In 2013, he participated in the development of the first similarity measure to exploit and demonstrate the usefulness of the description logic axioms in a biomedical ontology.

Andre Lamurias is a researcher at LaSIGE, currently enrolled in the BioSYS PhD programme at Universidade de Lisboa and holding a master's degree in Bioinformatics and Computational Biology from the same institution. His PhD thesis consists in developing text-mining approaches for disease network discovery and systems biology. More specifically, his research work is mainly focused on understanding how textual data from document repositories such as PubMed can be explored to improve our knowledge about biological systems.

Semantic Similarity Functions and Measures

Giuseppe Pirrò, ICAR-CNR, Rende, Italy

Introduction

The origin of similarity studies stems from psychology and cognitive science where, during the years, different models have been postulated. The *geometric* model enables to assess similarity between entities by considering them as points in a dimensionally organized metric space. Similarity is given by the distance between objects in this space; the closer together two objects, the more similar. The *feature-based* model, relies on features (i.e., characteristics) of the examined objects and assumes that similarity is a function of both common and distinctive features (Tversky, 1977). Other techniques for assessing similarity, such as Information Content (Resnik, 1995), Pointwise Mutual Information (PMI), Information Retrieval (IR) (Turney, 2001; Pirrò and Talia, 2008) Normalized Google Distance (Cilibrasi and Vitanyi, 2007) and Latent Semantic Analysis (Landauer and Dumais, 1997), leverage probability co-occurrence of words in large text corpora such as the World Wide Web. Yet others rely on structured information (Pirrò, 2012).

Upon these models a plethora of computational methods has been developed, which includes very intuitive approaches where similarity is computed by counting the number of edges/nodes separating two words in a network structure (Rada et al., 1989) but also more sophisticated ones where similarity is assessed by projecting the feature-based model of similarity into the information-theoretic domain (Pirrò, 2009). For a more practical point of view, semantic similarity is relevant in many research areas in computer science and artificial intelligence (Rissland, 2006). For instance, in databases, it is used to estimate similarity between entities (Kashyap and Sheth, 1996). In information retrieval, it is used to improve accuracy of the vector-space model (Lee et al., 1993; Hliaoutakis et al., 2006). In the biomedical domain, there exist some applications to compute semantic similarity between concepts of ontologies such as Gene Consortium (2004) or MeSH (e.g., Pedersen et al., 2007; Lord et al., 2003) with the aim to assess, for instance, protein functional similarity. In Zhang et al. (2007), an approach for clustering research papers annotated with MeSH descriptors is presented. In Natural Language Processing, similarity is useful in many contexts such as word sense disambiguation (Leacock et al., 1998; Ravi and Rada, 2007). Word similarity has been also used to compute similarity between short sentences (Li et al., 2006), determine semantic orientation of adjectives (Hatzivassiloglou and McKeown, 1997) and classify reviews (Turney, 2002).

The Semantic Web is one of the most active community in which similarity is being used. Similarity helps to compute mappings between different ontologies (Pirrò et al., 2008; Atencia et al., 2011), repair ontology mappings (Meilicke et al., 2007) or compute similarity between whole ontologies (Araujo and Pinto, 2007). Similarity and Formal Concept Analysis can be exploited to structure a particular domain of interest useful in ontology development (Formica, 2008). Similarity measures have also been revisited in the context of Description Logics (DLs), which are expressive languages with a formal semantic (Borgida et al., 2005).

Similarity is such a versatile tool that it has found its way even in Peer to Peer networks where it can be exploited to build semantic overlay networks of peers. Concepts of a shared taxonomy, used to semantically annotate content, can be seen as indicators of the expertise of a peer. Semantic similarity allows to compute neighbours on a semantic basis, that is, by computing similarity among peer expertises. The neighbours to route a given message to can be chosen by computing the semantic similarity between concepts in a query and those reflecting neighbours' expertises (Hai and Hanhua, 2008; Pirrò et al., 2010; Penzo et al., 2008).

This paper is built around two main objectives. The first is to survey on computational methods to assess semantic similarity. This will hopefully pave the way toward a comprehensive overview on the most popular similarity measures. In particular, similarity measures exploiting different *sources of knowledge* in the process of likeness estimation will be reviewed. The second objective is to describe a concrete implementation of the analyzed measures in an off-the-shelf tool extensible and freely available. In this respect, although some initiatives exist, they only deal with similarity measures exploiting a single source of knowledge therefore lacking in integrating and providing a flexible environment to be easily embedded in concrete applications.

Knowledge-based similarity measures will be reviewed in Section "Knowledge-Based Approaches" whereas those relying on search engines as source of knowledge will be analyzed in Section "Search-Engine-Based Similarity Measures". A possible extension of similarity measures to compute similarity between sentences is described in Section "A Strategy to Compute Similarity between Sentences". The architecture of the *Similarity Library* will be sketched in Section "The Similarity Library" whereas in Section "Related Work" it will be compared with related initiatives. Some concluding remarks and possible ongoing work will be discussed in Section "Concluding Remarks and Future Work".

Similarity Measures Between Words

This section provides an overview on the similarity measures implemented in the *Similarity Library*. For each measure, the main characteristics will be described. As an example accompanying the presentation of the different measures, the excerpt of the Gene Ontology Consortium (2004) depicted in Fig. 1 will be used.

Fig. 1 An excerpt of ontology.

Knowledge-Base Approaches

Knowledge-based approaches can be divided in two main categories, that is, network-based approaches and information-theoretic approaches. In the following, network-based approaches will be reviewed.

Network-based approaches

Network-based approaches to similarity exploit some semantic artifacts closely akin to the semantic model devised by Quillian (1968), where concepts are represented by nodes and relations by links. Usually in semantic networks, concepts are stored within a hierarchical structure following the principle of *cognitive economy*. Cognitive economy refers to the fact that *properties* of concepts are stored at the highest possible level in the hierarchy and not re-represented at lower level.

An important definition when working with semantic networks is that of most specific common abstraction (MSOA), which is the most specific ancestor concept subsuming two concepts in the structure. As an example, in Fig. 1 the msca between *Cellular Response* and *Detection of Stimulus* is *Response to stimulus*. However, in some cases two concepts can have more than one common ancestor since it is common for semantic networks to be modeled as a Directed Acyclic Graph (DAG).

The Rada measure

The work by Rada et al. (1989) computes distance between concepts in a hierarchical structure by considering the number of links separating them. In particular, the lower the number of links the more similar the two concepts. The next equation represents this measure.

$$D_{rada}(c_1, c_2) = \min_{edge}(c_1, c_2) \quad (1)$$

For instance, in Fig. 1, the distance between the concepts *UV Protection* and *Detection of Stimulus* is 5 whereas that between *Cellular Response* and *Detection of Stimulus* is 1, which indicates that *Cellular Response* is more similar to *Detection of Stimulus* than to *UV Protection*.

The Leacock and Chodorow measure

The Leacock and Chodorow measure (L&C) Leacock and Chodorow (1998) assesses similarity by considering the shortest path between the two concepts being compared (using node counting) along with the depth of the taxonomy. The following formula

reflects this measure.

$$sim_{L\&C}(c_1, c_2) = -\log \frac{\min_{node}(c_1, c_2)}{2 \cdot Depth} \quad (2)$$

It can be noted that even if this measure takes into account the depth, it only considered the maximum depth in the taxonomy and not the depth of the concepts being compared. Hence, the couples *Cellular Response- Detection of Stimulus* and *Regulation of bio. process-Localization* will be rated at the same similarity level.

The Wu and Palmer measure

The Wu & Palmer measure (W&P) [Wu and Palmer \(1994\)](#) calculates similarity by considering the depths of the two nodes in the taxonomy, along with the depth of the msca. The following formula reflects this measure.

$$sim_{W\&P}(c_1, c_2) = \frac{-2 \cdot Depth(msca(c_1, c_2))}{Depth(c_1) + Depth(c_2)} \quad (3)$$

Returning to our previous example, with this measure the similarity between *Cellular Response* and *Detection of Stimulus* is 0.66.

Information Theoretic Approaches

Information-theoretic approaches provide an alternative way to compute similarity in a semantic network. Here, the notion of Information Content (IC), which quantifies the informativeness of concepts, is adopted. IC values are obtained by associating probabilities to each concept on the basis of its occurrences in large text corpora. In the specific case of hierarchical structures, probabilities are cumulative as we travel up from specific concepts to more abstract ones. This means that every occurrence of a concept in a given corpus is also counted as an occurrence of each concept containing it. IC values are obtained by computing the negative likelihood of encountering a concept in a given corpus as reported in the following formula.

$$IC(c) = -\log p(c) \quad (4)$$

where c is a concept and $p(c)$ is the probability of encountering c in a given corpus. Note that in the case of hierarchical structures this method ensures that IC is monotonically decreasing as we move from the leaves of the structure to its roots. In fact, the concept corresponding to the root node of the isa hierarchy has the maximum frequency count, since it includes the frequency counts of every other concept in the hierarchy. For instance, in [Fig. 1](#) it can be noted that the IC (In [Fig. 1](#) values of *intrinsic* and *extended* IC are reported. These two notions will be discussed in Sections “Intrinsic information content” and “Extended information content”) of the concept *Biological Process* is almost equal to zero since it is a very abstract concept (the top of the hierarchy), whereas that of more specific concepts such as *Signal Transduction* or *Localization* is higher. Note also that leaves have IC equal to 1 as they represent completely described concepts (no children).

The Resnik measure

[Resnik \(1995\)](#) was the first to leverage IC values for the purpose of semantic similarity. The basic intuition behind the use of the negative likelihood is that the more probable a concept is of appearing in a corpus the less information it conveys, in other words, infrequent words are more informative than frequent ones. Once IC values are available for each concept in the considered ontology, semantic similarity can be calculated. According to Resnik, the similarity depends on the amount of information two concepts have in common. This shared information is given by the msca, that is, their subsumer. As an example, in [Fig. 1](#) the concept *Regulation of Biological Process* subsumes both *Negative Regulation of Cellular Process* and *Regulation of Homeostatic Process*. In order to find a quantitative value of the shared information we must first discover the msca. If one does not exist then the two concepts are maximally dissimilar, otherwise the shared information is equal to the IC value of their msca. Resnik’s formula is modeled as follows:

$$sim_{res}(c_1, c_2) = \max_{c \in S(c_1, c_2)} IC(c) \quad (5)$$

where $S(c_1, c_2)$ is the set of concepts that subsume c_1 and c_2 . Returning to our previous example, the similarity between the couples *Carbohydrate Utilization-Cellular Process* and *Localization-Regulation of Biological Process* are 0.002 and 0.1088 respectively. Starting from Resnik’s work, the [Jiang and Conrath \(1997\)](#) and the [Lin \(1998\)](#) similarity measures, which take into account the IC of the two concepts as well, have been proposed.

The Jiang and Conrad measure

The Jiang and Conrad measure (J&C) [Jiang and Conrath \(1997\)](#) is a semantic distance measure and is derived from the edge-based notion of distance with the addition of the IC as a decision factor ([Jiang and Conrath, 1997](#)). The next equation represents this measure.

$$D_{J\&C}(c_1, c_2) = 2 \cdot IC(msca(c_1, c_2)) - (IC(c_1) + IC(c_2)) \quad (6)$$

Returning to our example, according to the J&C measure the distances between the couples *Signal Transduction-Regulation of Homeostatic Process* and *Response to UV-Negative Regulation of Cellular Process* are 0.603 and 0.516 respectively. Note that in this case the lower the distance the higher the similarity. The J&C measure solves the problem faced with Resnik’s measure with which every two couples having the same msca have the same similarity.

The Lin measure

According to Lin “The similarity between c_1 and c_2 is measured by the ratio between the amount of information needed to state the commonality of c_1 and c_2 and the information needed to fully describe what c_1 and c_2 are”. Formally this formula is given in the following equation:

$$sim_{Lin}(c_1, c_2) = \frac{2 \cdot sim_{res}(c_1, c_2)}{IC(c_1) + IC(c_2)} \quad (7)$$

The Lin measure represents another variant of Resnik’s measure that takes into account the IC of the two concepts being compared. This measure of similarity has been designed according to the following principles: i) The similarity between c_1 and c_2 is related to their commonality; ii) the similarity between c_1 and c_2 is related to the differences between them and iii) the maximum similarity between c_1 and c_2 is reached when c_1 and c_2 are identical. The Lin measure returns 0.71 and 0.838 as values of similarity for the couples *Signal Transduction-Regulation of Homeostatic Process* and *Response to UV-Negative regulation of Cellular Process*, respectively.

Intrinsic information content

The classical way of measuring information content of concepts is based on the idea of combining knowledge of the hierarchical structure in which they are defined with statistics on their actual usage in text derived from a large corpus. The intuitive motivation behind this type of reasoning is that rare concepts are more specific and therefore much more expressive. However, from a practical point of view, this approach has two main drawbacks:

1. It is time consuming since it implies that large corpora should be parsed and analyzed. Moreover, the considered corpora have to be adequate in term of content to the considered semantic structure,
2. It heavily depends on the type of corpora considered and its size. It is arguable that IC values obtained from very general corpora maybe different than those obtained with more specialized ones. As for WordNet, the Brown corpus is typically exploited, which is a good source of general knowledge. However, if we were calculating similarity between concepts of very specialized ontologies such as MeSH, it is likely that Brown corpus does not contain many of the terms included in that ontology and then IC values and corresponding similarity assessments could be affected.

Research toward mitigating these drawbacks has been proposed by [Seco et al. \(2004\)](#). Here, values of IC of concepts rest on the assumption that the taxonomic structure of the ontology is organized in a meaningful and structured way, where concepts with many hyponyms (i.e., sub-concepts) convey less information than concepts that have a lower number of hyponyms. With this reasoning leaves are maximally informative. The intuition is: More abstract concepts are more probable of being present in a corpus because they subsume so many other ones. If a concept has many hyponyms, then it has more of a chance of appearing since the subsuming concept is implicitly present when reference to one of its hyponyms is made. So if one wanted to calculate the probability of a concept it would be the number of hyponyms it has plus one (for itself) divided by the total number of concepts that exist. The *intrinsic* IC for a concept c is defined as:

$$iIC(c) = 1 - \frac{\log(hypo(c) + 1)}{\log(max_{con})} \quad (8)$$

where the function *hypo* returns the number of hyponyms of a given concept c . Moreover max_{con} is a constant that indicates the total number of concepts in the considered structure. In [Fig. 1](#), values of *iIC* are reported for each concept. As it can be noted, concepts higher in the hierarchy have lower *iIC* values. Moreover, the more hyponyms a concept has the lower is its *iIC*. For instance, *Cellular Process* has an *iIC* equals to 0.091 whereas *Biological Regulation* has a higher *iIC* (i.e., 0.108).

The intrinsic IC formulation is based on the assumption that the ontology is organized according to the principle of *cognitive saliency* ([Zavaracky, 2003](#)). Cognitive saliency states that humans create concepts when there is a need to differentiate from what already exists. As an example, in WordNet the concept *cable car* only exists because its lexicographers agree that *cable* is a sufficiently salient feature (This feature indicates that the *cable car* operates on a cableway or cable railway as the WordNet gloss mentions.) allowed it to be differentiated from *car* and promoted to a concept in its own right. Obviously, what is cognitively salient to one community may not be to another and consequently these communities will have different similarity judgments. Hierarchies are usually created trying to cover lexical concepts following principles of general knowledge ([Seco, 2005](#)). The *Similarity Library* exploits this formulation for all the IC-based measures.

Extended information content

The intrinsic IC described above, results very useful in determining to what extent two concepts are related by subsumption relations. However, an ontology usually contains relations beyond inheritance that can be very useful to better refine the extent to what two concepts are alike. With this reasoning in mind, the Extended Information Content (*eIC*) has been introduced ([Pir  and Euzenat, 2010a](#)). The *eIC* is a score assigned to each concept computed by investigating the different kinds of relations a given concept has with other concepts. For instance, by only focusing on isa relations, in the example in [Fig. 1](#) we would lose some important information (e.g., that *Signal Transduction* is part-of *Cell Communication* or that *Signal Transduction* is part-of *Cellular Response*) that can help to further characterize commonalities and differences between concepts. For each concept, the coefficient

EIC is defined as follows:

$$EIC(c) = \sum_{j=1}^m \frac{\sum_{k=1}^n iIC(c_k \in C_{R_j})}{|C_{R_j}|} \quad (9)$$

This formula takes into account all the m kinds of relations that connect a given concept c with other concepts. Moreover, for all the concepts at the other end of a particular relation (i.e., each $c_k \in C_{R_j}$) the average iIC is computed. This enables to take into account the expressiveness of concepts to which a given concept is related in terms of their information content. The final value of *Extended Information Content* (eIC) is computed by weighting the contribution of the iIC and EIC coefficients thus leading to:

$$eIC(c) = \zeta iIC(c) + \eta EIC(c) \quad (10)$$

Where the two parameters ζ and η are used to weight the contribution of isa relations and other kinds of semantic relations. In Fig. 1, the eIC of the different concepts is reported. As it can be noted, in many cases the value is different from the iIC since in computing eIC all the semantic relations between concepts are considered. This score offers the same nice properties as the iIC as it can be directly extracted from the ontological structure. The *Similarity Library* also provides eIC values for each concept.

Hybrid approaches

Hybrid approaches usually combine multiple information sources or different models to assess similarity.

The Li measure

An approach combining structural semantic information in a nonlinear model is that proposed by Li *et al.* (2003). This work borrows some ideas from Shepard's law of generalization, which states that similarity decreases with distance following an exponential function Shepard (1987). Li *et al.* empirically defined a similarity measure that uses shortest path length, depth and local density in a taxonomy. If the two concepts are the same the similarity is equal to 1 else it is given by the formula reported in the following equation:

$$sim_{Li}(c_1, c_2) = e^{-\alpha l} \frac{e^{\beta h} - e^{-\beta h}}{e^{\beta h} + e^{-\beta h}} \quad \text{if } c_1 \neq c_2 \quad (11)$$

Where l is the length of the shortest path between c_1 and c_2 in the graph spanned by the isa relation and h is the level in the tree of the msca from c_1 and c_2 . The parameters α and β represent the contribution of the shortest path length l and depth h . The optimal values for these parameters, determined experimentally, are: $\alpha=0.2$ and $\beta=0.6$ as discussed in Li *et al.* (2003).

Returning to our previous example, the similarity between *Detection of Stimulus* and *Cell Communication* is 0.67. However it should be noted that this measure requires the tuning of two parameters.

Features and information content for similarity

This category of similarity measures, combines two models of similarity, that is, features and information content. The main idea is to exploit the IC formulation of similarity, in which the msca of two concepts c_1 and c_2 reflects the information these concepts share, and to extend it for considering also specific concept features (refer to Pirrò, 2009 for a detailed discussion on the feature-based model of similarity). Recently, a similarity measure combining features and information content that adopts Tversky's contrast model has been defined (Pirrò, 2009). The next equation reflects this measure.

$$sim_{P\&S}(c_1, c_2) = 3 \cdot IC(msca(c_1, c_2)) - IC(c_1) - IC(c_2) \quad (12)$$

In the case in which $c_1 = c_2$, the measure returns 1 as similarity value. This measure treats similarity between identical concepts as a special case and can give as output negative values, which makes it difficult the interpretation of results. Therefore, a new similarity measure, called *FaITH*, based on the Tversky ratio-model, has been defined in Pirrò and Euzenat (2010a). The next equation reports this measure.

$$sim_{FaITH}(c_1, c_2) = \frac{IC(msca)}{IC(c_1) + IC(c_2) - IC(msca)} \quad (13)$$

Similarity values returned by the P&S measure for the couples *Signal Transduction-Regulation of Homeostatic Process* is 0.456 whereas with FaITH the similarity value is 0.366. The main contribution of these two measures is that they enable to project the well-known feature-based similarity model into the information content domain and then to provide an alternative way to treat concept features.

Search-Engine-Based Similarity Measures

Search engines are without any doubt a huge source of knowledge that can be exploited in the process of similarity estimation. Differently from semantic-network based approaches, similarity measures exploiting search engines have to deal with unstructured knowledge. Even if there exist a huge amount of literature concerning distributional approaches to semantic similarity such as Latent Semantic Analysis (LSA) (Landauer and Dumais, 1997), here we will focus on more practical approaches for two main reasons. First, methods such as LSA require a corpus of content to be indexed on which applying the *Singular Valued Decomposition*

method. Since the *Similarity Library* is not tied to an specific corpus or application, implementing the LSA approach would make the library losing its generality. Second, the aim of the *Similarity Library* is to provide a scalable and portable tool to be used even in large scale applications and therefore, it has to be simple and immediately usable. Implementing LSA, on the other hand, would require to use large information repositories.

In the remainder of this section, two strategies implemented in the *Similarity Library* that make usage of search engines to estimate similarity will be reviewed.

The PMI-IR measure

PMI-IR [Turney \(2001\)](#) is a unsupervised learning algorithm for recognizing synonyms, based on statistical data acquired by querying a Web search engine. PMI-IR uses Pointwise Mutual Information (PMI) and Information Retrieval (IR) to measure the similarity of pairs of words. PMI-IR has been designed with the aim of identifying synonyms. In particular, PMI-IR has been evaluated on TOEFL synonymy tests where, given a base word (called *problem*), the goal is that of finding the more similar word among four choices (each of which is referred to as a *choice*). In the general case, PMI-IR computes its score according to the following formula:

$$PMI - IR_{score}(c_1, c_2) = \frac{p(c_1 AND c_2)}{p(c_2)} \quad (14)$$

where the function $p(\cdot)$ returns the probability of the problem/choice and it is computed by counting the number of query hits returned by a search engine (i.e., AltaVista in the original formulation). The author starting from this basic formula defined four different scores of increasing complexity. The first score assesses word similarity by focusing on the simple co-occurrence of words. The second score looks at words that co-occur in the same document and are close together. The third score faces the problem of antonym (i.e., opposite) noun scoring. Finally, the fourth score takes context into account.

As an example let's consider the following TOEFL question: Given the four words *thief*, *traitor*, *shark* and *discourage* which of these words is the most similar in meaning to the word *turncoat*? In the following table the steps performed by PMI-IR for answering this question are reported ([Table 1](#)).

As it can be noted, PMI-IR $score_1$ returns the higher score for the word *traitor*, which is indeed the most similar word to *turncoat*. This approach has been extensively compared with latent Semantic Analysis (LSA) in [Turney \(2001\)](#) and an improvement in performance in the same task of synonymy recognition has been reported.

The NGD measure

Normalized Google Distance (NGD) [Cilibrasi and Vitanyi \(2007\)](#) distance is a measure of semantic interrelatedness derived from the number of hits returned by the Google search engine for a given set of keywords. Keywords with the same or similar meanings in a natural language sense tend to be "close" in units of Google distance, while words with dissimilar meanings tend to be distant. In more detail the NGD between c_1 and c_2 is defined as follows:

$$NGD(c_1, c_2) = \frac{\max\{\log f(c_1), \log f(c_2) - \log f(c_1, c_2)\}}{\log N - \min\{\log f(c_1) - \log f(c_2)\}} \quad (15)$$

where $f(c)$ denotes the number of pages containing c , and $f(c_1, c_2)$ denotes the number of pages containing both c_1 and c_2 while N the number of pages indexed by the search engine. Returning to the example presented in the previous section, NGD returns the scores reported in [Table 2](#).

As it can be noted, even the NGD choices the correct alternative among the four words.

A Strategy to Compute Similarity Between Sentences

The similarity measures described in Section "Similarity Measures between Words" can be adopted to compute semantic similarity between sentences. Sentence similarity, is very useful in many research areas such as text summarization. However, most of current approaches exploit the classical vector space model ([Salton et al., 1975](#)), which fails when there are sentences semantically similar even if syntactically different as in the case, for instance, of the two sentences *I own a car* and *I have an automobile*. Therefore, by leveraging measures of semantic similarity, the aim is as follows: given two input sentences, calculate their similarity at semantic level. In particular, similarity between single words, is extended in the case of multiple words given that, the similarity between two

Table 1 An example of PMI-IR computation by using Google

Query	Hits X and Y	Hits Y	Score ₁
turncoat AND thief	2360	1,770,000	0.0013
turncoat AND traitor	5590	1,880,000	0.0029
turncoat AND shark	2280	2,740,000	$8 \cdot 10^{-4}$
turncoat AND discourage	1290	4,330,000	$2.97 \cdot 10^{-4}$

Table 2 An example of NGD computation by using Google

<i>Couple</i>	<i>NGD</i>
turncoat-thief	0.340
turncoat-traitor	0.4219
turncoat-shark	0.296
turncoat-discourage	0.1913

sentences can be seen as a function of the similarity of their component words. The approach described here is based on the following observations:

- Current approaches to compute sentence similarity using knowledge-based methods (e.g., Mihalcea *et al.*, 2006; Li *et al.*, 2006) only compute similarity between nouns in the sentences underestimating the importance of other parts of speech (e.g., adjectives and adverbs). To cope with this aspect the *Similarity Library* implements strategies to compute similarity also between verbs, adjectives and adverbs, respectively (refer to Pirrò and Euzenat, 2010b for more details).
- In a sentences there are some words that can contribute to a greater extent to the similarity of the sentences. For instance, specific words should have a greater impact than more general ones.

Let consider the following two sentences as example:

- Sentence 1 (s_1): *When the team and his trainer entered the city, some of the fans started to blame the latter.*
- Sentence 2 (s_2): *When the players returned into the city with the trainer, some supporters begun to yell at the latter.*

The general approach, adopted to compute sentence similarity, is inspired by the maximum weighted matching problem in a bipartite graph and consists in comparing all the words in two sentences to find their best coupling. In the maximum weighted matching problem, a non-negative weight $w_{i,j}$ is assigned to each edge $e(x_i, y_j)$ and the aim is to seek a perfect matching M to maximize the total weight $w(M)$. However, couples of nodes that are not matched should not participate in the final similarity calculation.

The process starts by construing a similarity matrix which has as rows words in the first sentence, and as columns words in the second sentence. In particular, to each element (representing a pair of words) is assigned a score, which is the similarity between the words. The score can be computed using one, or a combination, of similarity measures described in Section “Similarity Measures between Words”.

This matrix is fed in input at the *Hungarian* algorithm, which gives as output the best coupling of elements in rows and columns. After having obtained the best pairing, in order to give more emphasis to specific words and less to more general ones, the following coefficient of specificity is adopted:

$$spec_{e(i,j)} = \frac{IC(w_i) + IC(w_j)}{2} \quad (16)$$

This coefficient takes into account the average IC of the two words that have been matched (refer to Pirrò and Euzenat, 2010b for more details). Since the IC is an indicator of the informativeness of words, a pair with a higher *spec* is more specific and then can be more significant in estimating sentence similarity. At this point, we can compute sentence similarity as follows:

$$sem_{SEN}(s_1, s_2) = \sum_{i \in S_1} \sum_{j \in S_2} \frac{e(i,j) * spec_{e(i,j)}}{K} \quad (17)$$

where each $e(i,j)$ is the best weight for a couple of words $w_i \in S_1$ and $w_j \in S_2$ and K is the number of pairs with $e(i,j) > 0$. Recalling our previous example, Fig. 2 shows the pair matching found by the algorithm. The similarity between s_1 and s_2 is therefore $sem_{SEN}(s_1, s_2) = 0.7113$ by using the P&S measure. The result obtained, for the same sentence by PMI-IR and NGD are 0.641 and 0.643 respectively.

The Similarity Library

This section describes the implementation of a similarity library gathering the techniques reviewed in this paper. The library is available at (see “Relevant Websites section”).

Architecture

The *Similarity Library* is composed by a set of software modules implemented in Java. Table 3 summarizes the similarity measures implemented.

The overall architecture is depicted in Fig. 3. As it can be noted the architecture is built upon three layers. The *Data Layer* interacts with the different sources of knowledge that can be used to estimate similarity. The following table details the version of

Fig. 2 Example of sentence pair matching.

Table 3 Measures implemented by the *Similarity Library*

	Information exploited				Specific techniques
	Depth	Length	IC	SE	
Rada <i>et al.</i> (1989)		X			Shortest path counting edges
L&C Leacock and Chodorow (1998)	X				Path counting nodes and depth of the hierarchy
W&P Wu and Palmer (1994)	X				Depth of concepts and msca
Li <i>et al.</i> (2003)	X	X			Hybrid measure
Resnik (1995)			X		IC of the msca
Lin (1998)			X		IC of the msca and concepts
J&C Jiang and Conrath (1997)			X		IC of the msca and concepts
P&S Pirrò and Seco (2008); Pirrò (2009)			X		Mapping of features into IC
FaITH Pirrò and Euzenat (2010a)			X		Mapping of features into IC
PMI-IR Turney (2001)				X	Search engines hits
NGD Cilibiasi and Vitanyi (2007)				X	Search engines hits

the knowledge sources used in the current release of the library. The various knowledge sources can be easily updated since the library provides the proper parsers (Table 4).

The *Wrapping Layer* receives the information parsed by the *Data Layer* and transforms it into an internal model suitable for indexing. In more detail each data item (e.g., ontology concept) is assigned a Lucene (see “Relevant Websites section”) document composed by different fields. Subsequently, all the documents are stored in a disk index. This will be useful to speed up the lookup process needed during the similarity estimation. This will also enable an easier use of the library as compared to other initiatives (e.g., WordNet::Similarity Pedersen *et al.*, 2004) that require a relational databases and other software to be installed.

Finally, the *Similarity Layer* takes care of computing the similarity between the words or sentences passed in input. This is the highest layer of the architecture and represents the interface by which an application requires a similarity computation and receives the answer.

Software Architecture

This section provides some details about the classes implemented in the *Similarity Library* with the aim to give a hint on its internal software architecture. This will help in extending it with both new word and sentence similarity measures. Fig. 4 shows how the classes involved in the process of sentence similarity computation interact. The *Sentence Similarity Measure* interface provides basic definitions of methods that can be implemented by any sentence similarity strategy.

Common methods to any implementation are provided in the *Abstract Sentence Similarity Measure* class. In particular this class uses the *Sentence Utilities* class that provides methods to perform some preprocessing on the sentences being compared (e.g., tagging). Moreover, this class also uses the *Word Similarity Calculator* class that provides similarity scores for couples of words according to different similarity strategies such as search engine, by using the *Search Engine* assessor class, or WordNet, by using the *Word Net Assessor* class.

Fig. 5 details the structure of classes involved in the process of similarity estimation for knowledge-based approaches. Even in this case, an interface (i.e., *Similarity Measure*) provides some guidelines on the methods to be implemented by either IC-based and

Fig. 3 Architecture of the similarity library.

Knowledge source	Version
WordNet	3.0
MeSH	2009
Gene Ontology	OBO 1.12

path-based approaches. Common methods useful to any implementation are implemented by the two abstract classes *Abstract ICE*

Fig. 4 Classes involved in sentence similarity.

Similarity Measure and *Abstract Topological Similarity Measure*. Note that both classes use the *Abstract Index Broker* class, which provides access to the different ontologies stored in the corresponding Lucene indexes. Upon these two abstract classes, six additional classes provide similarity computation for each of the considered categories and ontologies. Finally, for each ontology a corresponding assessor class encompasses both the IC-based and path-based approaches.

In Fig. 6 it is reported the class diagram for search-engine based approaches. As in the case of knowledge-based approaches, an interface is defined (i.e., *Search Engine Similarity*) to provide some guidelines for concrete implementations. The *Abstract Search Engine Similarity Measure* provides common functionalities shared by the two approaches implemented and described in Section "Search-Engine-Based Similarity Measures". Note that the library provides implementations relying on two search engines (i.e., Google and Yahoo). The *Search Engine Assessor* provides a common point for using the different measures. Finally, Fig. 7 shows the main classes involved in the indexing process. As it can be noted, there is an interface and an abstract class along with different concrete implementations. In particular, for the WordNet ontology, four different indexes are constructed, one for nouns, one for verbs, one for adjectives and one for adverbs. Two additional indexes, one for the Gene Ontology and one for MeSH are also constructed.

Related Work

There exist some work in the literature related to the *Similarity Library*. The WordNet::Similarity library described in Pedersen et al. (2004) is implemented in Python and aims at computing relatedness between concepts. An online interface is made available (see "Relevant Websites section"), which enables to compute the similarity between words and to choose the strategy to be used. It is also possible to locally install this library after installing Python along with a relational database.

Fig. 5 Classes involved in knowledge-based word similarity.

Fig. 6 Classes involved in the similarity computation for search-engine-based approaches.

Fig. 7 Classes involved in the indexing process.

While sharing some commonalities with the *Similarity Library* such as the usage of WordNet and the implementation of several similarity measures, there are several differences. First, the *Similarity Library* is entirely written in Java and the it can be easily embedded in an existing piece of standalone Java code. Second, it is an off-the-shelf tool, and therefore there is no need to install interpreters (Python) or databases. This is because the ontologies used by the *Similarity Library* have been indexed through the Lucene IR library and then are portable without requiring any installation procedure. Third, the *Similarity Library* is a comprehensive tool to compute similarity between concepts belonging to different ontologies, not only WordNet. Besides, the *Similarity Library* also provides two search-engine based similarity strategies that can easily be combined with ontology based approaches.
